Figure 12.10. The % of *Placopecten magellanicus* byssally attached in relation to shell height. A, under natural conditions: regression calculated for 493 scallops in the size range 70–120 mm shell height, collected from L'Etang Harbour in August, 1967. B, under laboratory conditions: cumulative attachment of 424 scallops to a fibreglass surface during 40 days in the laboratory. (From Caddy 1972).

This has subsequently been confirmed in several studies using scallop species (e.g., Pesch and Stewart 1980; Martoja et al. 1989).

In the early stages after larval settlement the byssus functions to anchor spat in a clean, silt-free environment. In some species, like *Chlamys islandica*, which live in areas where the maximum current velocity above the seabed may exceed the swimming speed of the scallop (Gruffydd 1976b), it continues to serve this function throughout life. Since

Figure 12.11. The effect of temperature on byssal attachment of *Placopecten magellanicus* (size range 60–100 mm shell height). Percent - % scallops byssally attached to gravel after 7 days. Threads - the number of byssus threads secreted per scallop in 7 days. (From Caddy 1972).

byssus attachment inhibits swimming (Caddy 1972; Soemodihardjo 1974), the retention of a functional byssus in some of the more mobile species may serve to reduce dispersal of juvenile scallops away from favourable settlement areas (Minchin 1992).

12.4.2 Recessing

After releasing the byssus, many scallops recess into saucer-shaped depressions in the seabed, typically so that the upper (left) valve is level with or just below the surface of the sediment. The process of recessing in *Pecten maximus* was first described in detail and photographed by Baird (1958) and his observations have subsequently been confirmed in numerous other studies (e.g., Minchin 1978, 1992; Fleury et al. 1996; Maguire et al. 1999a, 2002b; Minchin et al. 2000). In *P. maximus* a series of powerful adductions eject water from the mantle cavity in the region of the posterior auricle, the water jets being directed downwards by muscular control of the velum. This may cause the scallop to swing round but also lifts the shell at an angle to the seabed so that subsequent water jets blow a hollow in the sediment. When this is of sufficient depth, a more powerful adduction lifts the scallop and it lands precisely in the recess. Sediment disturbed in the process settles on top of the shell and more accumulates from water jets directed downwards around the edge of the shell. After a few days a layer 5 mm thick may be present, making the position of the scallop difficult to detect when the valves are closed.

Figure 12.12. The effect of temperature on byssus attachment of *Aequipecten opercularis*. Time taken to reach 20, 50 and 80% byssal attachment at different temperatures. Mean values with 95% confidence limits. (From Paul 1980b).

The precision with which the recessing process is carried out indicates that recessing is a complex, closely-coordinated, behaviour pattern in *Pecten maximus*. Recessing usually starts soon after the scallop is exposed on the seabed. Once recessing commences, it takes from 2–20 minutes for *P. maximus* to complete the process and spat as small as 6–10 mm shell length have been seen to recess by this method (Minchin 1978, 1992; Minchin et al. 2000).

There are widespread reports of many other unattached scallops living in similar depressions on suitable soft substrates, including *Adamussium colbecki* (Berkman 1994), *Aequipecten opercularis* (Chapman et al. 1979), *Amusium pleuronectes* (Morton 1980), *Argopecten gibbus* (Allen and Costello 1972), *A. purpuratus* (Illanes-Bucher 1987), *Mizuhopecten yessoensis* (Tyurin 1990; Sakurai and Seto 2000), *Pecten fumatus* and *Equichlamys bifrons* (Olsen 1955; Young and Martin 1989), *Pecten novaezelandiae* (Tunbridge 1968) and *Placopecten magellanicus* (Caddy 1968; Stokesbury and Himmelman 1995b), but none of these authors provide a good description of the recessing process. Indeed, although *Pecten fumatus* and *Equichlamys bifrons* may occur in typical

saucer-shaped depressions, Olsen (1955) is emphatic in stating that these scallops do not bury themselves. An alternative mechanism to account for the formation of recesses in *Placopecten magellanicus* is given by Grant et al. (1993). In flume experiments, these authors found that for scallops with the ventral margin facing upstream, sediment was eroded from a horseshoe-shaped trough around the ventral margin of the shell, and deposited in two elongated crests at each end of the trough and on the auricles and dorsal margin of the scallop shell. Based on these observations they suggest that recesses are formed by the interaction between passive sediment transport and active excavation of sediment by the scallop. In view of the enormous number of observations that have been made on different scallop species worldwide, the absence in the literature of any good description of a rapid, closely-coordinated, recessing process, similar to that repeated observed in *Pecten maximus*, suggests that passive sediment transport may be an important component of recess formation in many species, particularly those that do not normally recess. For example, *Aequipecten opercularis* does not normally recess but some individuals, heavily encrusted with epifauna, have been observed in typical depressions (Chapman et al. 1979). Similarly, *Argopecten irradians* usually remains on the surface of the substrate but has been reported to recess in coarse sand, especially in winter (Belding 1931; Waller 1969) when scallop activity is low and water currents may be elevated. Recessed scallops are generally unattached but about 40% of recessed *Placopecten magellanicus* are anchored by a byssus to shell fragments in the sediment (Caddy 1968), and recessed spat of *Pecten maximus* is often similarly attached (Minchin 1992). Tank experiments have shown that *Pecten maximus* move frequently and disperse widely when placed on a concrete bottom, but recess rapidly, with little movement, when on sand (Baird 1958). In Strangford Lough, unrecessed *Pecten* moved about more regularly but recessed individuals stayed in the same position for an average of 27 days, probably moving only when disturbed (Hartnoll 1967). It is of interest to note that this average duration of stay in one position is remarkably similar to that of 31 days calculated for byssally attached *Chlamys islandica* in a Norwegian fjord (Vahl and Clausen 1980).

Following disturbance by predators or fishing gear, and after reseedling in culture operations, the speed of recessing of *Pecten maximus* is an important factor in reducing vulnerability to predation by visual predators such as crabs, fish and octopus. Recessing may reduce predation by camouflaging the scallop against visual predators but this is of limited value on grounds where the major predators of adult scallops are starfish, which detect their prey by chemosensory mechanisms. However, the layer of sediment on the upper valve may confer some protection from starfish by restricting contact with the tube feet, and it also reduces the settlement of epifauna on the shell, which may both reduce competition with epifaunal filter feeders and improve swimming performance. In recent years the rate of recessing of *Pecten maximus* has been frequently used as a quantitative test of scallop vitality in studies of the ecological impact of dredging (Maguire et al. 1997, 1999a, b, 2002a, b), and to assess methods for reseedling scallops on the seabed in aquaculture (Fleury et al. 1996, 1997).

Whatever the mechanism of recess formation, for many scallop species there may be important benefits of living in a recess associated with feeding. Studies of the gut contents of various scallops, including *Argopecten irradians* (Gutsell 1931; Davis and

Marshall 1961), *Aequipecten opercularis* (Hunt 1925; Aravindakshan 1955; Christensen and Kannevorff 1985; Lawrence 1993), *Mizuhopecten yessoensis* (Imai 1980; Mikulich and Tsikhon-Lukanina 1981), *Pecten maximus* (Lawrence 1993) and *Placopecten magellanicus* (Shumway et al. 1987), have generally found both pelagic and benthic food species, together with variable quantities of detritus. Scallops live at the sediment-water interface and appear to be opportunistic filter feeders, taking advantage of benthic organisms and material deposited on the surface of the sediment, as well as particles suspended in the near-bottom water (Shumway et al. 1987). When scallops recess, the inhalant water current is lowered to at least the level of the sediment surface and benthic material can be more easily drawn into the mantle cavity. Detritus and material falling from the water column will tend to collect in the depressions excavated by the scallops, particularly in areas with strong current flow, and this will increase the supply of available food. In a comparative study of the feeding mechanism of *Pecten maximus* and *Aequipecten opercularis* in a strongly tidally-mixed area of the north Irish Sea, Lawrence (1993) found that resuspended benthic diatoms were present in the benthic boundary layer throughout the year and comprised the major dietary item of both species. Planktonic diatom species were only available, and present in the gut contents, in spring and early summer. She concluded that *P. maximus*, which usually recesses, probably receives a lower quality diet than the unrecessed *A. opercularis* since *P. maximus* draws in water from nearer the sediment surface and take in more detritus. Comparative laboratory experiments showed that *P. maximus* has higher clearance rates and exhibits greater particle selection than *A. opercularis*, but is more sensitive to resuspended sediment in the diet. *Argopecten irradians* has been reported to re-suspend the surface sediments by vigorous shell clapping activity (Davis and Marshall 1961). This mechanism would operate more efficiently in recessed scallops and may be widespread in other species. Filter feeding in scallops, as in all bivalves, depends on relatively weak currents through the mantle cavity generated by the ctenidia, and is inhibited in strong water currents (e.g., Kirby-Smith 1972; Wildish et al. 1987, 1992; Wildish and Kristmanson 1988; Wildish and Saulnier 1993; Pilditch and Grant 1999). This suggests that, in areas with very strong current flow, efficient feeding may only be possible for recessed scallops. In such areas, recessing will also provide a limited form of anchorage, preventing the scallop from being washed away by the current.

12.4.3 Orientation

Scallops on the seabed live with the commissure plane horizontal and the morphological right valve underneath. If they get turned over they are able to regain the normal position by a special movement known as the righting reflex (Dakin 1909; Buddenbrock 1911). In this, water is ejected downwards by a powerful adduction in such a way that the shell flips over into the correct orientation. Young scallops generally right themselves with one adduction but older scallops may require several successive attempts (Minchin 1992). The speed of righting of *Pecten maximus* has been used as a measure of stress in recent studies of reseeded and the ecological impact of fishing (Minchin et al. 1999, 2000; Maguire et al. 2002a, b).

Some scallops appear to control their orientation with regard to the direction the shell is facing. Hartnoll (1967) found that the orientation of *Pecten maximus* in Strangford Lough was non-random, with recessed scallops tending to orientate so that the ventral shell gape faced directly into the tidal flow, which in this area is virtually unidirectional (Figure 12.13a). A similar orientation with respect to water currents was noted by Caddy (1968) for a population of *Placopecten magellanicus* in the Gulf of St Lawrence. In two more typical locations, where the direction of tidal flow reverses, Mathers (1976a) found a tendency for *Pecten maximus* to orientate to either of two directions (Figure 12.13b and c). Approximately half the population faced the ebb current while the other half faced the flood current, and individual scallops did not change position when the tidal flow changed direction. This apparently imposed a rhythm of feeding and digestion in these scallops, phased to the tidal cycle, with scallops facing the ebb current being 6 h out-of-phase with those facing the flood current. Such orientation to a water current probably increases the efficiency of filter feeding. With the ventral shell gape facing into the flow, tidal currents will assist mantle cavity ventilation because the water is moving past the scallop in a direction that complements both the inhalant and the exhalant ventilatory stream of the scallop (Figure 12.14). However, various more recent studies have often failed to find clear orientation in the field or have produced conflicting results. Thus, MacDonald and Bajdik (1992) studied two populations of *Placopecten magellanicus* and found that one population oriented so that at least a portion of the inhalant margin was directed into the prevailing current, while the other population was randomly orientated. Stokesbury and Himmelman (1995b) found that sea scallop orientation was random in two natural beds and at three sites used for tag-release experiments, two of which were on gravel substrates and one on sand. However, tagged scallops released on bedrock were significantly orientated so they concluded that, although sea scallops have the ability to orient, they do not do so on gravel and sand substrates if current velocities are less than 18.3 cm s^{-2} . More complex relationships between scallop orientation and current speed have also been found for the Japanese scallop, *Mizuhopecten yessoensis*, by Sakurai and Seto (2000), who concluded that orientation to flow maximised filtration and avoided dislodgement.

Scallops that do not recess may also orientate to currents but there have been few observations. Chapman et al. (1979) and Chapman (1981) report underwater observations that unattached *Aequipecten opercularis* also orientate so that the ventral gape faces into the current. Thorburn and Gruffydd (1979) found no evidence for this in experimental studies in a flume, but found instead that *A. opercularis*, made lethargic by high temperatures, tended to be passively orientated with the hinge facing upstream at higher water velocities. In similar flume experiments on *Chlamys islandica* (Gruffydd 1976b) and *Placopecten magellanicus* (Grant et al. 1993), the hydrodynamically stable passive orientation at higher current flows was also with the hinge facing into the current. When the tentacles of *C. islandica* were fully extended, the dorso-ventral axis of the scallops in these experiments was directly aligned in the direction of the current, but with the tentacles withdrawn the shell rotated in an anticlockwise direction by about 40° . When byssally attached in this orientation the elongated anterior auricle would make it impossible for the shell to be overturned by strong currents (Stanley 1970), but it would appear to be difficult for the scallop to feed efficiently as the water currents would directly

Figure 12.13. The orientation of *Pecten maximus* in relation to water currents. Diagrams showing the direction of orientation of the ventral shell margin of scallop populations in a) Strangford Lough, b) Kilkieran Bay, c) Galway Bay. The directions of ebb and flow tidal currents at each location are indicated by arrows. (Redrawn and modified from a) Hartnoll 1967 and b), c) Mathers 1976).

Figure 12.14. The life position and orientation of *Pecten maximus* in relation to water currents. In A), the direction of the water current complements the inhalant and exhalant streams of the scallop, in B), the directions are opposed. (From Mathers 1976).

oppose the exhalant ventilatory stream. The underwater observations of Olsen (1955), however, suggest that *Pecten fumatus* orientates with the hinge facing into the current in a strong tide but that orientation is haphazard in weaker tides. The occurrence of both active and passive components of scallop orientation (Grant et al. 1993), and the ecological significance of orientation in species with different life habits, is therefore not well understood and more detailed studies are required.

12.4.4 Swimming

The swimming behaviour of scallops is considered in some detail in Chapter 5 of this book, approached from a physiological viewpoint; this chapter concentrates instead on the more ecological aspects. The mechanism of swimming has been studied frequently in *Pecten maximus* (Antony 1906; Dakin 1909; Buddenbrock 1911; Bayliss et al. 1930;

Buddenbrock and Möller-Racke 1953; Baird 1958; Thomas and Gruffydd 1971; DeMont 1990; Fleury et al. 1996; Jenkins and Brand 2001) and *Placopecten magellanicus* (Caddy 1968; Dadswell and Weihs 1990; Manuel and Dadswell 1991, 1993, 1994; Parsons and Dadswell 1992; Parsons et al. 1992; Bowie et al. 1993; Carsen et al. 1994, 1995, 1996; Cheng et al. 1996; Cheng and DeMont 1996a, b; Kleinman et al. 1996; Lafrance et al. 2002). Other species have been studied in varying detail including *Adamussium colbecki* (Ansell et al. 1998), *Aequipecten opercularis* (Rees 1957; Moore and Trueman 1971; Stephens and Boyle 1978; Chapman et al. 1979; Thorburn and Gruffydd 1979; Chapman 1981; Ansell and Ackerly 1994; Jenkins et al. 2003), *Amusium balloti* (Joll 1989), *Amusium pleuronectes* (Morton 1980), *Argopecten gibbus* (Allen and Costello 1972), *A. irradians* (Belding 1931; Gutsell 1931; Moore and Marshall 1967; Ordzie and Garofalo 1980a; Peterson et al. 1982; Winter and Hamilton 1985; Guzik and Marsh 1989), *Chlamys hastata* (Guzik and Marsh 1990; Donovan et al. 2002), *C. islandica* (Gruffydd 1976b; Vahl and Clausen 1980; Brokordt et al. 2000a), *Euvola ziczac* (Brokordt et al. 2000b), *Mimachlamys asperima* and *Equichlamys bifrons* (Pitcher and Butler 1987), *Mizuhopecten yessoensis* (Dautov and Karpenko 1984; Sakurai and Seto 2000) and *Pecten fumatus* (Fairbridge 1953; Olsen 1955).

There have been a number of important comparative studies on the functional morphology and evolution of the swimming habit in scallops (Yonge 1936, 1953; Waller 1969; Stanley 1970), and special emphasis has been placed on allometric changes in muscular mechanics during growth (Gould 1971; Soemodihardjo 1974) and adductor muscle obliquity (Thayer 1972). These latter, largely theoretical, studies made inferences about the swimming abilities of different species that have been tested and discussed in subsequent experimental investigations of scallop hydrodynamics and behaviour (e.g., Moore and Trueman 1971; Gruffydd 1976b; Thorburn and Gruffydd 1979; Morton 1980; Vogel 1985; Dadswell and Weihs 1990; Hayami 1991; Manuel and Dadswell 1991, 1993, 1994; Millward and Whyte 1992; Ansell and Ackerly 1994; Cheng et al. 1996; Sakurai and Seto 2000). Most investigations of swimming have been carried out in laboratory tanks but particularly valuable observational and experimental studies have been carried out in the natural environment to determine reactions to environmental conditions, fishing gear and contact with predators in *Aequipecten opercularis* (Chapman et al. 1979; Jenkins et al. 2003), *Amusium balloti* (Joll 1989), *Argopecten irradians* (Moore and Marshall 1967; Peterson et al. 1982; Winter and Hamilton 1985), *Pecten maximus* (Baird 1958; Hartnoll 1967; Minchin 1992; Fleury et al. 1996) and *Placopecten magellanicus* (Caddy 1968; Parson and Dadswell 1992; Carsen et al. 1994, 1996).

Swimming responses appear to be very similar in all species. In addition to the righting reflex mentioned above, scallops utilise two locomotory escape responses, the jumping and swimming reactions (Figure 12.15) (Buddenbrock 1911; Thomas and Gruffydd 1971). During jumping, water is ejected from the ventral mantle margin and usually propels the animal hinge-line (dorsal) foremost. The shell adductions that produce these jets are few in number (usually 1–3), generate relatively low pressures in the mantle cavity (Moore and Trueman 1971), and recur at low frequencies so that the scallop, if it takes off at all, returns to the seabed between each adduction. During swimming, the scallop moves ventral edge foremost, propelled from the seabed by water ejected dorsally

Figure 12.15. (a) Scallop jumping and (b) swimming movements, indicating the direction of movement, and the position and direction of water jets.

on either side of the hinge in a rapid series of adductions that recur at a high frequency (2–5 adductions s^{-1}) and generate relatively high pressures in the mantle cavity. A wide gaping of the valves for 5–15 seconds characteristically precedes the swimming response, whereas the valves gape only momentarily before jumping. Swimming is therefore a more vigorous response and moves the scallop a greater distance than jumping.

In a typical burst of swimming (Figure 12.16a) the adult scallop takes off from the seabed and rises up into the water at an angle of about 30–50°, the trajectory then levels off and the scallop may swim more-or-less horizontally for a short distance before active swimming stops and the animal sinks passively to the seabed in a series of side-slips (Caddy 1968; Chapman et al. 1979; Morton 1980).

This type of jet propelled swimming is very effective in adult scallops, but has limitations in juveniles due to problems of scaling. In a detailed analysis of swimming in juvenile sea scallop of 5–30 mm shell height, Manuel and Dadswell (1993) describe three types of swimming. Very small sea scallops predominantly use stepwise swimming, which involves the alternation of two types of valve clap cycle, the up-clap and the over-clap, that alternate more vertical and more horizontal body angles in a step-like pattern. Small scallops develop so much lift that they ascend from the seabed at a very steep angle and often follow a spiral flight path with little horizontal displacement. However, since the maximum velocity that small scallops can attain by swimming is lower than the water currents they often experience on the seabed, staying up in the water column may be advantageous for maximising downstream movement. As sea scallops increase in size the stable swimming type progressively replaces stepwise swimming, with variable swimming occurring in a small proportion of animals in the intermediate size range. In stable swimming the shell is maintained at a relatively stable body angle, the angle of ascent declines, swimming velocity increases and the flight path levels out so that the scallops become increasingly capable of horizontal displacement under their own power. During stable swimming over-claps predominate but some scallops may execute an up-clap every fourth or fifth adduction (Figure 12.16b) to produce an undulating flight similar to that observed in some adult sea scallops by Caddy (1968). From their experimental and modelling studies Manuel and Dadswell (1993) conclude that sea scallops pass

Figure 12.16. Swimming in *Placopecten magellanicus*. a). The path taken during a typical single burst of swimming (From Caddy 1968). b). Undulating level swimming, showing up-claps and over-claps (From Manuel and Dadswell 1994).

a hydrodynamic threshold at a shell height of 12–16 mm, which they believe corresponds to the change from turbulent to laminar flow around the shell. Below this threshold swimming is energetically very costly, which may explain why very small sea scallops tend to remain byssally attached.

Some comparative data on the swimming performance of different scallops is given in Table 12.3. These values may not all be strictly comparable, as they were obtained by different workers using a variety of methods, but they do allow some assessment of swimming ability and of factors affecting swimming. *Amusium* was long presumed to be the most proficient bivalve swimmer, based on its morphological adaptations (Yonge 1936; Stanley 1970; Gould 1971; Thayer 1972), but until the investigations by Morton (1980) on *Amusium pleuronectes*, swimming had not actually been observed in any species. His results showed that, compared with the scallops previously studied, *A. pleuronectes* swam further, faster and appeared also to have the greatest endurance, as it made the largest number of adductions in one swimming burst. However, subsequent studies of *A. balloti* by Joll (1989) showed that this is an even better swimmer, for it swims substantially faster and more than double the maximum single-swim distance reported for *A. pleuronectes*. *Placopecten magellanicus* has an excellent shell shape for producing hydrodynamic lift (Gruffydd 1976b; Thorburn and Gruffydd 1979) and is an excellent swimmer: it swims at a similar speed to *A. pleuronectes* but makes fewer adductions per swim and travels a much shorter distance. *Aequipecten opercularis* is also relatively fast and has been frequently shown to be a very good swimmer. The information available for other species is more limited but *Pecten fumatus* and *Argopecten irradians*, in particular, also appear to be powerful swimmers.

Various factors affect swimming performance. Chapman et al. (1979) attributed the relatively poorer performance of the queen scallop *Aequipecten opercularis* in Loch Ewe, compared with queens in Claonaig Bay, to the presence of shell-fouling epifauna in Loch Ewe, which increased both weight and drag. This conclusion is supported by the experimental studies of Winter and Hamilton (1985), who found that weights added to the shell of *Argopecten irradians* caused a marked reduction in the distance travelled in a burst of swimming. They calculated that a weight equivalent to the maximum weight of shell epifauna (6 g) caused a 28% decrease in the distance travelled. In contrast, Jenkins and Brand (2003) found that the epifaunal load on the shell had no effect on the ability of *Aequipecten opercularis* to swim above the dredge mouth. Swimming performance also varies with body size but the relationships are not straightforward and vary among species. Several species that swim well as juveniles appear to lose the ability to swim during ontogeny (Yonge 1936; Olsen 1955; Baird and Gibson 1956; Caddy 1968; Waller 1969; Minchin and Mathers 1982). Gould (1971) attributes this to the inherent problems of scaling, which he and Thayer (1972) believe is partly counteracted in older scallops by allometric growth of shell and muscle. Morton (1980) refutes much of this analysis for *Amusium pleuronectes*, pointing out that although small individuals swim faster, the large individuals swim for longer periods of time and hence go farther. Distance travelled per swim also increases with body size in *Amusium balloti* (Joll 1989), *Aequipecten opercularis* (Chapman et al. 1979) and *Argopecten irradians* (Winter and Hamilton 1985), but decreases markedly in large *Placopecten magellanicus* (Caddy 1968) and *Pecten maximus* (Minchin and Mathers 1982). In contrast to *Amusium pleuronectes*, the swimming speed of *Amusium balloti* (Joll 1989), *Aequipecten opercularis* (Chapman et al. 1979) and *Chlamys islandica* (Gruffydd 1976b) increases with body size and, up to a certain size, it probably does also in *Placopecten magellanicus* for Caddy (1968) comments that sea scallops of 70 mm shell length and over can keep pace with fishing gear towed at 1–2 knots, while smaller individuals fall behind. However, sea scallops over 100 mm shell length are recessed and do not respond to approaching gear. Larger animals require an increased swimming speed if hydrodynamic lift is to compensate for increasing body weight (Gould 1971). Irrespective of differences in swimming performance, it would seem that, for most species, large individuals swim less often and require a higher threshold stimulus to elicit the swimming reaction (Baird and Gibson 1956; Caddy 1968; Allen and Costello 1972; Mathers 1976a; Morton 1980; Minchin and Mathers 1982). At the other end of the size range, swimming is also problematic, and energetically expensive, for very small scallops. This has been clearly demonstrated for *Placopecten magellanicus* (Manuel and Dadswell 1993, 1994) but the same factors may also apply in other species.

Taken overall, Table 12.3 shows that few scallops swim more than 1 m off the seabed or greater than 5 m distance in one swimming burst. On repeated stimulation the distance travelled in successive bursts of swimming falls sharply and an increasing proportion of scallops refuse to swim (Chapman et al. 1979; Winter and Hamilton 1985; Joll 1989). Chapman et al. (1979) found that very few *Aequipecten opercularis* made more than 8 consecutive swims, and none more than 11, and the mean cumulative distance travelled for all swims was only 6.6 m in Claonaig Bay and 3.5 m in Loch Ewe. For *Amusium*

balloti only one individual out of 55 tested could be stimulated to make 4 consecutive swims (Joll 1989), but this individual (93 mm shell height) achieved a cumulative distance of 27.4 m, while another individual (109 mm shell height) covered 30.8 m in two swims. Biochemical evidence suggests that the inability to undertake multiple swims is due to fatigue, rather than habituation to the stimulus; scallops take several hours to recover normal physiological functions after swimming to exhaustion (Gäde et al. 1978; Grieshaber 1978; de Zwaan et al. 1980; Thompson et al. 1980; Livingstone et al. 1981; Brokordt et al. 1999, 2000a, b; Jenkins and Brand 2001). It must therefore be concluded that, with the possible exception of *Amusium*, scallop swimming reactions involve rapid movements over very short distances. Such responses are well suited for escape reactions but are inappropriate for efficient long-distance swimming.

In addition to predators, scallop swimming reactions are known to be evoked or modified by certain environmental factors. *Argopecten irradians* swims more often, and for greater distances, when released on sand than in eelgrass patches (Winter and Hamilton 1985). In addition, over short distances (25 cm), bay scallops appear to be able to swim towards seagrass beds using visual information (Hamilton and Koch 1996). The mechanisms controlling these reactions are not known but such behaviour serves to aggregate bay scallops in their preferred habitat of seagrass beds, where conditions are possible better for feeding and avoiding predators. Water currents also affect swimming activity. Experimental studies of *Chlamys islandica* in a flume showed that all sizes swam more often at higher current speeds, or when current speed was raised, but swimming activity was suppressed when current speed decreased (Gruffydd 1976b). At all current speeds a greater proportion of the smallest size group became byssally attached and swam less frequently than the larger size groups. Gruffydd considered that these reactions to currents may be of ecological significance, leading to the inward movement of the larger animals in Norwegian fjords. However, observations in one fjord by Vahl and Clausen (1980) showed that a very high proportion of *C. islandica* is normally byssally attached (97%) and the frequency of movement is very low. They also comment that swimming reactions to the presence of a diver are less evident in periods when the currents are strong. *Aequipecten opercularis* may be induced to swim by stimulating the dorsal velum with a water jet from a syringe (Chapman et al. 1979), but no relationship was found between current speed and swimming frequency in laboratory experiments with this species (Thorburn and Gruffydd 1979). In contrast, Moore and Marshall (1967) recorded increased swimming activity in *Argopecten irradians* 1–2 hours after tidal reversals, which suggests that this was a current response.

Many scallop species react by swimming when approached by divers (Gibson 1956; Baird 1958; Moore and Marshall 1967; Vahl and Clausen 1980; Minchin and Mathers 1982; Parsons and Dadswell 1992) and by fishing gear (Olsen 1955; Caddy 1968; Chapman et al. 1979; Jenkins et al. 2003). When one scallop swims it often induces swimming in others nearby, setting off a chain-reaction (Chapman et al. 1979; Vahl and Clausen 1980; Minchin and Mathers 1982; Howell and Fraser 1984). These may be responses to stimulation by light, water currents or vibrations but there have been few experimental studies. Scallops have complex and sensitive eyes that can detect movements and shadows (Buddenbrock and Möller-Racke 1953; Land 1966).

Underwater observations of *Aequipecten opercularis* in Claonaig Bay, Scotland, showed that queen scallops responded to fishing gear by swimming at distances of 1–1.5 m and were only caught in trawls when off the seabed (Chapman et al. 1979). The importance of vision in stimulating swimming is evident from the fact that daylight catches in this fishery generally exceed those taken at night. Conversely, the active-swimming *Pecten fumatus* is more easily caught at night (Olsen 1962), but this difference is probably more a reflection of the different type of fishing gear used, than of differences in the reactions of the scallops, for the dredges used in this Tasmanian fishery capture scallops only when they are inactive. To fish successfully with dredges the boats generally work in formation in this fishery, and good catches are taken from a bed only after several hours dredging, when the scallops have become too fatigued to swim.

Surprisingly little is known about the seasonal variability of scallop swimming, though various studies in both the field and the laboratory have noted correlations between temperature and different components of swimming performance. Pitcher and Butler (1987), for example, recorded fewer escape responses by *Mimachlamys asperrima* in August at 11.4°C, than in April at 19°C. Scheibling et al. (1995) noted that active swimming of *Placopecten magellanicus* to approaching divers was observed in November at 6°C, but not in January and February when water temperature was ~0°C, and swimming started again as temperature increased to 5°C in March. Parsons and Dadswell (1992) also describe a very clear seasonal pattern of swimming activity for *Placopecten magellanicus*. They found that very few scallops swam in the winter months at temperatures of <4°C, but swimming increased in spring and summer to a maximum in late summer and autumn that corresponded with the annual temperature maxima. They also found that the clap rate during swimming correlated with temperature over the range 3–12°C. This confirmed previous laboratory studies on juvenile sea scallops by Manuel and Dadswell (1991), who also reported that mean and maximum swimming velocities correlated with temperature. Recently, Lafrance et al. (2002) investigated the effect of a thermal shock, such as might occur during a scallop reseeding operation. They found that clap rate and maximum number of claps per swim were significantly reduced following the sudden transfer of juvenile sea scallops from 18°C to 8°C, and although there was some subsequent acclimation, clap rate did not fully acclimate within 6 days. Clearly, many of the physiological properties of scallop adductor muscle are temperature dependent, as shown for *Argopecten irradians* by Olson and Marsh (1993) who reported that maximum velocity at zero force, and therefore maximal power output, increased significantly with temperature over the range 10–20°C. As well as swimming activity, the time taken to respond to stimuli before swimming can also vary with season. Ordzie and Garofalo (1980a) found that the response time of *Argopecten irradians* before swimming was significantly greater at 12°C than at 20°C, but that both predator recognition and swimming performance were temperature independent. In a more detailed study of seasonal variability in the swimming behaviour of *Aequipecten opercularis*, Jenkins et al. (2003) recorded the proportion of queen scallops that evaded dredge capture by swimming up into the water column to be captured in a net deployed above the dredge. They found a strong positive correlation with seawater temperature, and laboratory experiments indicated that the observed seasonal variability in dredge avoidance was probably the

result of changes in the time taken to respond to stimuli, rather than changes in the ability to perform a large number of valve adductions. In contrast, Jenkins and Brand (2001) found no seasonal variability in the response time of *Pecten maximus*.

Although the results of these various studies have been inconsistent, temperature clearly has a direct affect on scallop swimming behaviour through its effects on metabolic activity and nerve transmission. However, in all studies involving seasonal comparisons, the direct effects of temperature are confounded with other factors that vary seasonally, such as reproductive state, food supply and stored energy reserves. Seasonal cycles of reproduction, and energy storage and utilisation, are well known in scallops (see Thompson and MacDonald 1991), and the experimental manipulation of temperature in the laboratory has shown a positive relationship between temperature and the metabolic condition of the adductor muscle in *Placopecten magellanicus* (Kleinman et al. 1996). Brokordt et al. (2000a) showed that reproductive stage had no effect on the number and rate of valve claps performed by *Chlamys islandica*, although there was a reduction in the ability to recover from exhausting swimming activity during gonadal maturation and spawning. Similar results were obtained for *Euvola ziczac* (Brokordt et al. 2000b). Jenkins and Brand (2003) also found no effect of reproductive state on avoidance of dredge capture in *Aequipecten opercularis*. In *Pecten maximus* the reduction in adenylic energetic charge of the adductor muscle in response to the stress of dredge capture varied seasonally and was lowest in February, when glycogen levels in the muscle were at a minimum (Maguire et al. 2002c). Despite these various findings, confirmation of the direct role of temperature in causing seasonal variability in swimming performance requires further laboratory experiments to unconfound variability in seawater temperature with seasonal variability in the metabolic status of scallops, and to clarify which components of swimming behaviour contribute to the observed differences between seasons.

A proper understanding of seasonal variability in scallop swimming has important implications for both fisheries and aquaculture. In fisheries, the precise description of seasonal variations in swimming activity may allow more efficient use of different gear types and more effective gear to be developed. Furthermore, quantitative estimates of seasonal changes in catchability, such as those made by Jenkins and Brand (2003), will allow more reliable stock assessments to be made in studies using commercial or scientific catch rates as indices of population abundance. In aquaculture, knowledge of seasonal variations in swimming is important for successful bottom culture or sea ranching of scallops. Numerous studies have shown that juvenile sea scallops, reseeded on the seabed at high densities, disperse at a greater rate in the warmer months (e.g., Carsen et al. 1995; Hatcher et al. 1996), and similar results have been obtained for *Pecten maximus* (Fleury et al. 1996). Seasonal variability in scallop escape responses also affect the vulnerability of reseeded scallops to predation, and since predators are also affected by seasonal factors, the interactions are complex (Barbeau and Scheibling 1994c; Barbeau et al. 1994, 1996).

12.4.5 Reactions to Predators

It is very well known that contact with predators can induce an escape reaction in many scallops, and this behaviour has received increasing attention as the reseedling of juvenile scallops has become more frequent. Most reports of escape reactions have involved responses to asteroid starfish (e.g., Dakin 1909; Buddenbrock 1911; Lecomte 1952; Mellon 1969; Moore and Trueman 1971; Thomas and Gruffydd 1971; Soemodihardjo 1974; Bloom 1975; Stephens and Boyle 1978; Wilkens 1981; Dautov and Karpenko 1984; Chernoff 1987; Pitcher and Butler 1987; Jenkins and Brand 2001; Ortiz et al. 2003), or gastropod molluscs (Ordzie and Garofalo 1980a, b; Peterson et al. 1982; Powers and Kittinger 2002), and there is little evidence that strong reactions are induced by other important predators such as crustaceans and fish.

Scallops react to contact by a predator by closing the shell, jumping or swimming, three distinct responses of increasing intensity (Thomas and Gruffydd 1971). The response of *Pecten maximus*, *P. jacobaeus* and *Aequipecten opercularis* varies greatly with different species of starfish: a high proportion make vigorous escape movements (jumping or swimming) after contact by predatory starfish species such as *Asterias rubens*, *Astropecten irregularis* and *Marthasterias glacialis*, whereas non-predatory starfish like *Solaster papposus*, *Porania pulvillus* and *Henricia sanguinolenta* evoke more minor reactions, or none at all (Lecomte 1952; Thomas and Gruffydd 1971; Soemodihardjo 1974). A similar ability to discriminate between predatory and non-predatory gastropod molluscs has been demonstrated for *Argopecten irradians* (Ordzie and Garofalo 1980a). Such behavioural recognition of potential predators has been described for other molluscs groups (Bullock 1953) and may be a common feature of molluscan behaviour. To evoke the swimming reaction it is generally necessary for the starfish or gastropod to touch the mantle margin or tentacles of the scallop, which suggests that the response is chemosensory. The reactions to starfish are possibly mediated by surface-active agents, secreted by the tube-feet of the starfish (Feder and Lasker 1964), which have been identified as 'saponin-like' or, more specifically, as steroid glycosides (Mackie 1970; Mackie and Turner 1970). Nothing is known of the mechanism by which the gastropod predators of *Argopecten irradians* are selectively identified. It is likely that some scallop escape reactions to predators are also induced by visual stimuli (Uexküll 1912; Buddenbrock and Möller-Racke 1953; Morton 2001) or by tactile stimuli such as vibrations, but this has been mostly inferred from scallop escape reactions to divers and fishing gear (Olsen 1955; Caddy 1968; Chapman et al. 1979; Joll 1989; Jenkins et al. 2003). For most species, reactions to tactile stimuli are not as vigorous or as predictable as the response to physical contact by starfish. Since many scallop species appear to swim less readily as they get older (or bigger) (Baird and Gibson 1956; Caddy 1968; Allen and Costello 1972; Mathers 1976b; Morton 1980; Minchin and Mathers 1982; Parsons and Dadswell 1992; Jenkins et al. 2003) it might be expected that escape reactions to predators would also change during ontogeny. Morton (1980) postulates that such behavioural changes occur in *Amusium pleuronectes*, and that larger scallops rely more on sustained shell closure, rather than escape movements, to avoid predators. However, this conclusion is based mostly on functional interpretations of the

morphology, together with knowledge of changes in swimming performance with increasing size, and there have been few direct investigations. Thomas and Gruffydd (1971) concluded that the escape response to stimulation by *Asterias rubens* was independent of age for *Pecten maximus* from 3–8 years old, although their data suggests a decline in the response of the 7 and 8 year olds. More recently, Jenkins and Brand (2001) found that the time taken for *P. maximus* to respond to a starfish stimulus was significantly longer in larger (105–110 mm shell length), compared with smaller (80–95 mm) scallops. For *Aequipecten opercularis*, Soemodihardjo (1974) found no difference in the proportion of animals of different age groups that responded to *Asterias rubens* by swimming, but Jenkins et al. (2003) found a lower propensity to swim to avoid gear capture in larger individuals. Variations in swimming behaviour and ability with age and body size therefore differ among species and the relationships are not straightforward. Escape reactions are of considerable advantage to scallops in reducing predation. The ability to differentiate between potential predators and harmless species is clearly of great adaptive value for it minimises feeding interruptions and prevents energy being wasted in making unnecessary escape responses. This is particularly advantageous for species that recess (Thomas and Gruffydd 1971), or byssally attach (Vahl and Clausen 1980), for it saves these species the considerable additional energy cost of making a new depression or re-forming the byssus.

In recent years a number of studies have described mutualistic associations between species of *Chlamys* and various epizoid sponges, which act, together with the scallop escape reactions, to reduce predation by starfish. Such associations are amenable to manipulative experiments in laboratory tanks, or enclosures in the sea, in order to test the nature and ecological significance of the interaction between the species (Bloom 1975; Forester 1979; Chernoff 1987; Pitcher and Butler 1987; Pond 1992; Burns and Bingham 2002; Donovan et al. 2002). Epizoid sponges on the upper valve of the scallop greatly inhibit predation by starfish but some sponges are more effective than others (Pitcher and Butler 1987). The scallop probably derives benefit mainly because the presence of the sponges greatly reduces adhesion of the starfish tube-feet to the shell, but tactile camouflage may also be involved (Bloom 1975; Forester 1979; Chernoff 1987; Pond 1992). The interactions between species are clearly complex for the presence of sponges on the shell reduces the responsiveness of *Mimachlamys asperima* to contact by predatory starfish (Pitcher and Butler 1987), but does not appear to inhibit swimming in *Chlamys hastata* (Donovan et al. 2002). In addition to providing protection from predators, the presence of sponges on the shell may confer additional selective advantages for *Mimachlamys asperima* with crellid sponges on the shell have higher growth rates of shell and tissue than those without sponges (Pitcher and Butler 1987). Similar associations between scallops and other taxa, such as the epibiotic relationship between the hydroid *Hydractinia angusta* and the Antarctic scallop *Adamussium colbecki*, may also defend the scallop from predators (Cerrano et al. 2001).

12.4.6 Dispersal and Migrations

The final aspect of scallop behaviour to consider is the extent and nature of any population movements. Many fishermen all over the world believe that scallops migrate from one area to another and this view has occasionally received scientific support. Yonge (1936), for example, stated that *Aequipecten opercularis* and *Argopecten irradians* both 'make extensive migrations from time to time'. Numerous studies have recorded individual scallops, and occasionally whole populations, moving for distances that vary from a few metres to many kilometres, but there is, in fact, very little evidence to show that these movements are active, directed, migrations.

Tagging experiments have been carried out on several populations of *Pecten maximus* (Gibson 1953, 1956; Baird and Gibson 1956; Mason 1957; Murphy 1986; Brand and Murphy 1992; Allison 1993). They all show very little movement, with nearly all returns from the same bed or within 1–2 km of the point of release. However, the analysis of tag returns from a commercial fishery is not a very accurate technique for assessing such small movements as it is generally impossible to determine the precise position of recapture. Howell and Fraser (1984) made a more precise study by transplanting tagged scallops into a small area at very high density and recording subsequent dispersal from a fixed point by a series of diving surveys. They found that some 60% of the live tagged scallops were still within 30 m of the release point after 18 months, confirming earlier views that this species moves very little (Hartnoll 1967). More active swimming species such as *Placopecten magellanicus* may move rather greater distances but there is no evidence of extensive migration (Baird 1954; Dickie 1955; Posgay 1963, 1981; Melvin et al. 1985). Tag returns from Georges Bank, analysed by Posgay (1981), showed that 85% of recaptures were within 10 miles (16.1 km) of the release point. He suggested that adult *Placopecten* move very little, that the direction of swimming is probably random and any net movement with time is brought about by tidal currents. The larger tagging study by Melvin et al. (1985) confirmed and amplified these findings. They reported 52% of recaptures within 5 km, 77% within 10 km and 94% within 25 km of the release point; found that mid-sized scallops (60–89 mm) moved greater distances than smaller or larger size groups and used vector analysis to show that scallop movements followed closely the complex patterns in direction and velocity of water movements over Georges Bank, Browns Bank and the Great South Channel. Carsen et al. (1995) found that tagged juvenile *P. magellanicus* were much more mobile in the autumn but the net daily displacement was <3 m for more than 60% of the scallops recorded. *Mizuhopecten yessoensis* tagged in Japan moved an average of 5–8 nautical miles (9.3–14.8 km) in 59 days and the direction of this movement was attributed to strong currents (Imai 1980). Similarly, movements of *Argopecten irradians* have also been considered to be due to current transport (Belding 1931; Moore and Marshall 1967), though one recent study has shown that over very short distances (<25 cm) bay scallops are able to use visual information to swim towards seagrass beds (Hamilton and Koch 1996). *Chlamys islandica* swims more frequently in strong currents (Gruffydd 1976b) and current transport could account for the unusual distribution of this species in Norwegian fjords, with progressively older age distributions towards the upper reaches (Wiborg 1963).

Although byssally attached throughout life, this species does move about (Vahl and Clausen 1980) and recruitment to some populations is delayed for several years (Vahl 1981, 1982), but until recently there was little evidence that this movement of older scallops is a directed migration. However, Arsenault et al. (2000) tagged juvenile *C. islandica* on an inshore bed in the northern Gulf of St Lawrence and found that movement was consistently towards increasing depth, and not in the direction of the tidal currents. Although the mechanism controlling this downslope movement is not clear, this would appear to be the first experimental evidence indicating the directed movement of a scallop population away from a nursery area.

Most scallop species are not well-adapted for making extensive migrations: they swim for very short distances (see Table 12.3), become rapidly fatigued and take a long time to recover after swimming. When they swim in response to predators, divers or fishing gear the direction of swimming is usually directed initially away from the source of stimulation but the course is erratic (Caddy 1968; Chapman et al. 1979; Winter and Hamilton 1985; Joll 1989; Carsen et al. 1996). This leads to a random dispersal, but in areas of strong current flow there will be a tendency for swimming scallops to be carried downstream. Such random or downstream dispersal probably account for the majority of the scallop movements reported in the literature. When one scallop swims it often stimulates others nearby and this can lead to mass swimming activity in a population (Chapman et al. 1979; Vahl and Clausen 1980; Minchin and Mathers 1982; Howell and Fraser 1984). In strong currents these scallops may be carried for some distance downstream, stimulating each other to swim several times before they become exhausted. This could explain some of the examples of mobile species like *Argopecten irradians* and *Aequipecten opercularis* suddenly disappearing from a fishing ground (Belding 1931; Rees 1957; Rolfe 1973). Commercial fishermen often pull their gear along very precise 'tows', where the bottom topography is known to be suitable, so scallop populations may not need to be carried very far to become suddenly unavailable to fishing.

In scallops transplanted at high densities the aggregation of predators increases swimming escape responses and, together with the tendency to stimulate one another to swim, leads to a gradual dispersal. For adult *Pecten maximus* this dispersal is random, or downstream, and continues until the distance between individuals is sufficient to reduce these interactions to more natural levels (Howell and Fraser 1984). Several studies have investigated movements of juvenile *P. magellanicus* in bottom culture trials (e.g., Cliche et al. 1994; Giguère and Cliche 1994; Scheibling and Hatcher 1994; Carsen et al. 1995; Scheibling et al. 1995), and while dispersal is usually rapid, the general conclusion is that local hydrodynamics is not a reliable predictor of dispersion in natural habitats. Large numbers of juvenile *Mizuhopecten yessoensis* are regularly transplanted to prepared beds for cultivation in Japan (Ito 1991). These scallops generally remain in the area where they are released, but movements both inshore and offshore have been recorded, though the mechanisms responsible for these movements are not clear (Yamamoto 1951, 1953), or have been attributed to downstream advection (Goshima and Fujiwara 1994). Volkov et al. (1982) had similar difficulty accounting for the direction of movement of juvenile *M. yessoensis* transplanted in Vityaz Bay, Sea of Japan, but concluded that starfish played an indirect role by stimulating swimming and the scallops then tended to move into deeper

water 'for purely mechanical reasons'. They do not mention the direction of water currents in the area.

Dispersal into deeper water may also occur in populations of *Chlamys septumradiata* in the Clyde Sea area for young individuals have been found byssally attached in shallow areas and older animals live on the deep-water muds where there are few surfaces for attachment (Allen 1953). Golikov and Scarlato (1970) state that pre-spawning aggregations of *Mizuhopecten yessoensis* in the southern Primorje (Sea of Japan) move into very shallow water when temperatures increase in the spring and disperse again into deeper water in the winter. Insufficient information is available to explain these, or many other examples of apparent movements in scallop populations, but there is currently little direct evidence that any of these are active, directed, migrations. Minchin (1987) noted that *Pecten maximus*, unable to recess, consistently moved up the sloping sides of a large pond. Apart from the observations of Arsenault et al. (2000) on *Chlamys islandica* and Hamilton and Koch (1996) on *Argopecten irradians*, this would appear to be one of the only records of a directed movement in any scallop species but the ecological relevance of Minchin's observation is doubtful for the scallops were in very unnatural conditions, in much shallower water than they normally live. There is experimental evidence to support the movement of *C. islandica* into deeper water as they increase in size (Arsenault et al. 2000), but this is local-scale movement leading to spatial size partitioning within the same inshore bed, and the mechanism to account for this downslope movement is not known.

The strongest case for any large-scale migration in scallops is advocated by Morton (1980) for some members of the genus *Amusium*. Pointing out the many morphological adaptations of *Amusium* for efficient swimming, he puts the persuasive argument that 'it would seem ridiculous to suggest that such modifications arose simply to remove the scallop from the immediate proximity of a predator'. Instead, he argues, there is circumstantial evidence to suggest that two species of *Amusium* undergo active, seasonal migrations, coming in to the shallow coastal waters of Hong Kong to breed. This is based on the observation that both species appear in Hong Kong markets only when they are sexually mature, *A. pleuronectes* in the winter months and *A. japonicum* in the summer months, though the beam trawlers that catch these scallops fish in the same areas throughout the year. Morton himself admits that this is weak evidence of migration and fails to consider the alternative possibility that the seasonal appearance of mature scallops in the catch could result from a reduced ability to avoid capture when the gonads are full (however, recent studies have shown that reproductive state does not appear to affect swimming performance in *Aequipecten opercularis* (Jenkins et al. 2003)). There is also no support for seasonal migration in *Amusium* from tagging studies carried out in Australia on the related *A. balloti*; of 677 tagged scallops returned, only 14 had moved more than 10 km in up to 121 weeks at liberty (Williams and Dredge 1981). Despite the lack of sound evidence for migration, members of the genus *Amusium* have wide distributions throughout the Indo-Pacific region and are superbly adapted for a highly mobile mode of life, so extensive movements remain a possibility and field studies are urgently required to determine if these are directed movements that could be termed a migration.

12.5 FURTHER STUDY

Since the first edition of this book was published in 1991, knowledge of factors affecting the occurrence, spatial distribution and abundance of scallop populations has expanded very rapidly. As expected, the worldwide development of scallop culture, based on either the collection of naturally-produced larvae settling on artificial collectors placed in the sea after spawning, or on hatchery culture, has provided the impetus, the opportunity, and some useful methods for studying the biology of the larval and early post-larval stages of many species of scallop, and knowledge of these life-history stages has therefore increased enormously. Similarly, the development of bottom culture as a low-cost cultivation technique in many countries has stimulated extensive research on the ecology, physiology and behaviour of juvenile scallops, and on predator/prey interactions. Despite the wide scope and volume of this research there are inevitably many topics that require further study. Many of these have already been pointed out in the preceding sections but special mention should be made of some areas for research that are both important and timely.

Scallops have distinct habitat preferences, live in aggregated distributions and are relatively immobile so they are easily detected and caught in commercial or recreational fisheries. Ease of capture, combined with variable recruitment patterns, make scallops very vulnerable to overfishing and lead to 'boom and bust' fisheries. The high market value of scallops, and the decreasing availability of alternative fisheries as other stocks are overfished, result in high fishing effort and make it possible for boats to continue to fish for scallops at very low densities. In doing so, the heavy dredge gear used in most fisheries kills and damages many other animals on the seabed, changes the physical nature of sediments and modifies benthic habitats and communities (e.g., Dayton et al. 1995; Bradshaw et al. 2000; Brand 2000; Collie et al. 2000; Hall-Spencer and Moore 2000; Veale et al. 2000). In order to limit the widespread ecological impact of scallop dredging on benthic communities, and to provide more stable, economically efficient fisheries, there is growing evidence to suggest that the future of scallop fisheries may lie with closed area management (Horwood 2000). Rotational fishing of small closed areas, combined with predator clearance and stock enhancement, has long been part of the highly successful Japanese seabed cultivation of scallops (Ventilla 1982), and seasonal, rotational or permanent closures to bottom fishing, with or without stock enhancement, are increasingly being proposed or introduced to restore habitat, rebuild populations and manage scallop fisheries elsewhere (e.g., Dao and Carval 1999; Arbuckle and Metzger 2000; Murawski et al. 2000; Myers et al. 2000; Arnold 2001; Bradshaw et al. 2001). There have been some notable successes. Short rotational closures (<4 years), together with re-seeding, have been used with great success to increase yield-per-recruit, maintain a stable fishery and sustain full-time employment for scallop fishers in New Zealand (Arbuckle and Metzger 2000). On Georges Bank, scallop biomass increased 14-fold following a 4-year closure to mobile fishing gear, without stock enhancement (Murawski, et al. 2000). The success of these and other closures, together with pressure from conservation bodies to protect endangered species and habitats, will undoubtedly lead to the introduction of other closed areas in the coming years. These closures will be

fruitful fields for research. There has been a massive research effort on the ecological impacts of scallop dredging in recent years (reviewed in Jennings and Kaiser 1998; Bradshaw et al 2000), but there is relatively little information available on the recovery of benthic organisms, communities or habitats after closure to fishing (Collie et al. 2000; Bradshaw et al. 2001). Properly replicated large-scale experiments examining the time scale of recovery within closed areas are now urgently required so that closures can be designed to effectively manage fisheries and conserve benthic habitats. Research to determine the provenance of larvae and recruitment mechanisms is also essential so that closed areas are sited to protect sources of scallop recruitment, rather than sinks. Much of this knowledge is likely to come from the rapidly developing fields of biochemical and molecular genetics (Sweijd et al. 2000). Molecular genetic and immunological techniques are currently available that allow individual bivalve veliger larvae to be identified to species (e.g., Hu et al. 1992; Frischer et al. 2000; Paugam, et al. 2000), and with rapid developments in methods such as microsatellites, minisatellites and DNA sequencing it is becoming increasingly possible to carry out high resolution studies on sub-populations or stocks (Thorpe et al. 2000). Such techniques could be used to evaluate the extent to which closed areas export larvae, juvenile or adult scallops, and to assess the effectiveness of stock enhancement, particularly when the stock enhancement involves the transfer of scallops from other locations or from hatcheries. The molecular genetic techniques will also be available to be applied more widely, together with ecological investigations and oceanographic modeling, in multidisciplinary studies of recruitment mechanisms, which has long been one of the most challenging and intractable problems in scallop fisheries biology.

ACKNOWLEDGMENTS

I am grateful for the assistance and support of many colleagues but particularly my research assistants Bryce Beukers-Stewart, Stuart Jenkins, Belinda Vause and Mog Mosley. Chris Bridge assisted with the illustrations. I would also like to commend Sandy Shumway and Jay Parsons for their patience in waiting for the manuscript. It is a pleasure also to acknowledge the generous financial support provided by the Isle of Man Department of Agriculture, Fisheries and Forestry for much of my research on scallops.

Chapter 13

Scallops and Marine Contaminants

Peter J. Cranford

13.1 INTRODUCTION

The marine environment receives a wide range of industrial, agricultural and domestic wastes. Marine contaminants may have an immediate impact on local coastal communities, and may further interact with living resources in shelf waters as the contaminants are transported seaward. Coastal and shelf waters also receive direct inputs of contaminants from the atmosphere and from offshore industries. Contaminant exposure can induce a wide range of biological effects in organisms including biochemical, immunological, physiological, and bioenergetic responses to stress, altered growth and reproductive output, and histopathological effects. Depending on the exact nature and temporal and spatial scale of the biological response, impacts on individuals may have implications at population, community, and ecosystem levels. The Pectinidae have received considerable attention in studies of contaminant distributions and biological effects. Reasons for this attention include the fact that they are largely sedentary and unable to escape contaminant exposure, have a wide geographic distribution, appear to be relatively sensitive to a wide range of pollutants, and are commercially important.

The risk of any contaminant impacting epibenthic organisms (e.g., post-settlement scallops) is related to numerous physical, chemical and biological processes that are responsible for the contaminant reaching, and accumulating in the near seabed region. An important mechanism by which contaminants are transported in the marine environment is by scavenging (uptake) onto particulate matter and particle settling. As a result, marine sediments are a major sink for many trace contaminants. The slow release of contaminants from sediments can result in scallops being subjected to chronic exposure long after specific anthropogenic discharges cease. Once subjected to an acute or chronic exposure to a specific contaminant, the impact on scallops is related to contaminant bioavailability and the potential for bioaccumulation (amount accumulated in tissues) of toxicants. The former requires a process by which the contaminant is taken up and the latter is related to the rates of uptake and loss of contaminants that can vary greatly for different contaminants and organisms. Scallops, as suspension feeders, may be exposed directly to dissolved and particulate contaminants in the water column, or indirectly through their food sources. As a result of scavenging onto particulate matter, concentrations of contaminants in solid form are often several orders of magnitude greater than the solute concentration. Particle ingestion is therefore an important means for the uptake of particle-reactive contaminants (including most metals and organic contaminants) by scallops. With large volumes of water entering the mantle cavity and

passing the gills during feeding, scallops are also highly susceptible to the passive assimilation of bioavailable contaminants. This direct uptake of soluble contaminants is generally orders of magnitude greater than the amount assimilated indirectly with solid food.

This paper reviews research on different classes of anthropogenic contaminants as they relate to the Pectinidae, but is not meant to be an exhaustive literature review. Owing to the large number of potential pollutants, each section of this review focuses on specific contaminants that have received a relatively high degree of research interest over approximately the past decade. Much of the earlier research on scallops was reviewed by Gould and Fowler (1991). In order to avoid simply identifying numerous *perceived* risks to scallops from a very wide range of human activities, an attempt has been made, where possible, to discuss the *real* risk to populations by (1) integrating laboratory biological effects data with knowledge of the capacity of scallops to adapt to contaminant exposure, (2) identifying major oceanic processes known to enhance or reduce chronic contaminant exposure, (3) providing information on environmentally relevant exposure conditions, and (4) comparing the perceived zone of impact with the distribution of local scallop stocks. This approach, which relies on specific geographical case studies, is intended to emphasise contaminant issues of foremost importance to scallop stocks.

13.2 TRACE METALS

Even though many trace metals are essential to organism metabolism, all are capable of causing a wide range of deleterious effects in marine organisms and populations at concentrations that are only slightly higher than typically found dissolved in seawater (Rainbow 1993). Metals can be taken up by scallops passively through diffusion from the surrounding water and from food ingestion and absorption. Protein binding of metals prevents the outward diffusion from tissue, leading to accumulation in the body if metal uptake exceeds excretion. There is considerable variability in biological responses (harmfulness degree, type of response and degree of bioaccumulation) to metallic contaminants, even among similar zoological groups and life-stages (Berthet et al. 1992). All bivalve molluscs have the ability to accumulate large amounts of trace metals in their tissues. As a result, exposure of scallop stocks to trace metals could make them toxic to their predators, including humans.

Cadmium, a nonessential trace metal, is recognised as one of the most deleterious metallic contaminants and has somewhat dominated the inorganic trace metals literature pertaining to scallops in recent years. Much of the oceanic input of cadmium from rivers and atmosphere is believed to be from anthropogenic origin (Neff 2002). Cadmium tends to bind weakly to particles and much of the oceanic pool is bioavailable. Members of the Pectinidae appear to accumulate cadmium to a higher degree than other organisms studied (Gould et al. 1985; Evtushenko et al. 1990; Lukyanove et al. 1993; Viarengo et al. 1993), indicating the absence of an effective mechanism for regulating tissue concentrations. Cadmium levels in the hepatopancreas and kidney were observed to increase with age in the Japanese scallop *Mizuhopecten yessoensis* (Evtushenko et al. 1990; and Lukyanove et al. 1993), and in tissues associated with the digestive gland of the Antarctic scallop

Adamussium colbecki (Mauri et al. 1990; Viarengo et al. 1993), and the sea scallop *Placopecten magellanicus* (Uthe and Chou 1987). The digestive gland was found to contain 91% of the total cadmium accumulated by *P. magellanicus* (Uthe and Chou 1987). The very high cadmium content stored by *A. colbecki* from isolated regions around Antarctica appears to be related to the relatively high cadmium concentrations in seawater upwelled from the deep Southern Ocean (Viarengo et al. 1993). It is interesting to note that the amount of cadmium in *P. magellanicus* tissues was higher for animals from offshore sites (Georges Bank and Browns Bank, Canada) than at coastal sites receiving substantial anthropogenic cadmium input (Uthe and Chou 1987). This illustrates the importance of natural factors such as the local food supply or primary productivity in contributing to tissue cadmium levels in scallops (Bryan 1973).

There are marked differences in the ability of scallops to regulate the concentration of different metals stored in tissues. While cadmium is not effectively regulated by scallops and continues to accumulate with age (above), many other trace elements remain at constant levels as the animal grows, an indication that these metals are highly regulated by the scallop. Lukyanove et al. (1993) provided evidence to support homeostasis of the essential trace elements zinc and copper in *M. yessoensis*, and Gould et al. (1988) provided support for the tight regulation of magnesium in *P. magellanicus* gonad. Cadmium exposure and accumulation has been shown to cause the redistribution of essential trace metals (e.g., copper, zinc and iron) present in *M. yessoensis* tissues, and this disruption to metals homeostasis may interfere with metabolism and enzymatic activity (Chelomin et al. 1995). Similarly, *P. magellanicus* exposed to cadmium altered zinc, manganese, and copper homeostasis in the kidney, potentially permitting toxic responses to these previously sequestered metals (Fowler and Gould 1988).

Fishery products can be screened for potential hazard to humans by comparing metals content in edible tissues with calculated risk-based concentrations (RBC). The RBC for cadmium in tissues, calculated based on consumption of 54 g day⁻¹ for 175 days year⁻¹ by an adult, is 13.5 µg g⁻¹ dry weight (Neff 2002). This RBC is generally less than the majority of values detected in scallop tissue, which ranges from 0.58 to 43.6 µg Cd g⁻¹ dry weight (Berkman and Nigro 1992; Neff 2002, and calculated from data in Uthe and Chou 1987). For these cadmium stores to be a hazard to consumers, including humans, they must be in a bioavailable form. Cadmium stored in tissue as solid concretions are not bioavailable to consumers and are nontoxic to the scallop (Neff 2002). Such concretions have been described in the kidney of *Argopecten irradians* and in *P. magellanicus* following cadmium exposure (Carmichael and Fowler 1981; Fowler and Gould 1988), but were not observed in *A. colbecki* that are known to accumulate large amounts of cadmium (Nigro et al. 1992). The other major tissue store for metals is binding to soluble ligands such as metallothioneins. The fraction of total accumulated cadmium in the digestive gland of *Pecten jacobaeus* and *A. colbecki* that was bound to metallothionein was reported to be 60% and 30%, respectively (Viarengo et al. 1993). Lukyanove et al. (1993) and Stone et al. (1986) reported that metallothionein does not play a significant role in cadmium accumulation in *M. yessoensis* and *Pecten maximus*. Most of the cadmium accumulated (72–99%) in *M. yessoensis* was found to bind to high-molecular-weight proteins (Evtushenko et al. 1986; Evtushenko et al. 1990; Syasina et al. 1994). Maximal

cadmium accumulations in male *M. yessoensis* gonad were determined to be associated with high-molecular-weight proteins, while accumulations in female gonad were primarily associated with medium-molecular-weight proteins (Syasina et al. 1994). Evtushenko et al. (1986) noted that after 30 days of exposure of *M. yessoensis*, cadmium was redistributed from high-molecular-weight proteins to metallothionein-like proteins. The binding of cadmium to these macromolecules renders them nontoxic to the scallop and to predators (Viarengo et al. 1993; Neff 2002).

Although scallops are strong accumulators of potentially hazardous metals, total body concentration is not a good indicator of either metals toxicity to the scallop, or of the danger to consumers. The detoxification of metals by binding to proteins or to insoluble granules greatly reduces levels of harmful metabolically available metals in scallop tissues, and limits the potential for biomagnification up the food chain. There is little evidence to support biomagnification of cadmium, or other inorganic trace metals, in the marine environment (Gray 2002; Neff 2002).

13.3 TRACE ORGANICS

Trace organic contaminants entering the sea from anthropogenic sources include a diverse range of compounds including organometals, organophosphates, organohalogens, and other compounds with endocrine-disrupting properties (Moore et al. 2002). Many of the compounds of concern are relatively lipophilic, resulting in a high propensity for the contaminant to leave the aqueous environment and accumulate in biota or the organic fraction of sediments. The primary means of uptake of lipophilic compounds is directly from the surrounding water, rather than from food, and a major route of intake by bivalves is through the gill. An important concern associated with trace organics is the effect on biota of long-term, low level exposure. The potential for chronic effects is particularly high for those toxic compounds that are mobile and persist in the environment for many years. Such compounds include many organochlorine insecticides (DDT, dieldrin, toxaphene and chlordane), PCBs, dioxins, brominated flame retardants, polychlorinated naphthalenes, and chlorinated paraffins (Moore et al. 2002). Unlike trace metals, the degree of accumulation of organic contaminants in bivalve tissues is generally closely linked to biological responses. Stress from organic contaminant accumulations in tissues may cause immunotoxicity, impaired reproduction, carcinogenicity, increased susceptibility to disease and parasites, and eventually mortality (Moore et al. 2002). In addition to biological damage, there are also potential hazards associated with contaminant biomagnification and health concerns for humans ingesting toxic organic bioaccumulations in seafood.

The treatment of vessels and other marine structures with anti-fouling biocides has resulted in the accumulation of toxic contaminants in scallops, leading to impacts at the population level. Organotin paint, mainly bis-(tri-*n*-butyltin)-oxide (TBT), has been shown to be detrimental to the growth and survival of juvenile *Pecten maximus*, but not to adults (Paul and Davies 1986). Juvenile *P. maximus* have been observed to progressively increase TBT accumulations during chronic exposure, and depuration is slow with 60–80% remaining after eight weeks (Davies et al. 1986). In contrast, oysters tend to

accumulate less TBT than scallops and rapidly eliminate the body burden soon after the exposure ceases (Davies et al. 1986). The adductor mussel appears to be the primary storage site for TBT in scallops (Davies et al. 1986). Minchin et al. (1987) monitored the settlement of bivalves and the organotin content of adult scallops in different bays in Ireland during an eight-year period. The body burden of TBT in adult scallop tissue was higher than in other species tested and was greatest near known sources of TBT. The settlement of the scallops *P. maximus*, *Lima hians* and *Chlamys varia* onto collectors in Mulroy Bay either failed or was greatly reduced during years when TBT was used to treat salmonid cage netting (Minchin et al. 1987). Although other factors may also be implicated in the observed temporal variations in scallop recruitment off Ireland (Minchin et al. 1987), these observations appear to indicate that the known effect of TBT on juvenile scallops resulted in changes in scallop populations prior to the ban on the use of TBT paint for many applications. The TBT issue did not disappear with the more limited allowable application of this product, but remains a concern for organisms residing near major shipping lanes, offshore installations and shipyards.

Bivalve filter-feeders are known to be highly sensitive to hydrocarbon contaminants over a concentration range as low as 0.03–3.0 mg L⁻¹ (Widdows et al. 1981, 1987, 1995; Axiak and George 1987; Stekoll et al. 1980). Two- and three-ring aromatic hydrocarbons, with a molecular weight cut-off at fluoranthene, and aliphatic hydrocarbons of less than *n*-C₁₁ are the primary sources of hydrocarbon toxicity to *Mytilus edulis* (Widdows and Donkin 1989, 1992). Cranford et al. (1999) showed *P. magellanicus* to be highly sensitive to a low aromatic content mineral oil composed of aliphatics less than *n*-C₁₈. High mortality and negative growth (resorption of gonad) were observed during chronic exposure to just 0.03 mg L⁻¹ mineral oil. The total hydrocarbon body burden at the end of this 37-day exposure was relatively high at 1,143 µg g⁻¹ dry tissue weight (i.e., strong accumulator) and the digestive gland was the primary hydrocarbon storage site (Cranford et al. 1999).

Hydrocarbon-growth relationships indicate growth reductions in *M. edulis*, the most extensively studied bivalve species in this regard, occur when tissue dose exceeds 0.1–1 µg g⁻¹ dry tissue weight (Widdows and Donkin 1989; Widdows et al. 1995). Reductions in scope-for-growth during exposure to hydrocarbons appear to be attributed primarily to reductions in particle clearance rate, but increased energy utilisation is also a significant contributing factor (Axiak and George 1987; Widdows et al. 1987; Cranford et al. 1999). Total polyaromatic hydrocarbons (PAHs) measured in the pink scallop, *Chlamys rubida*, from bays “oiled” by the *Exxon Valdez* crude oil spill in Alaska in March 1989 averaged 0.29 µg g⁻¹ (maximum of ~1.2 µg g⁻¹) in 1989, but decreased by a factor of 15 to background levels by 1990 (Armstrong et al. 1995). Based partially on these scallop data, these authors concluded that large marine oil spills do not negatively affect fauna residing in shelf areas deeper than 20 m.

Orimulsion[®], a newly developed bitumen-based fuel is used by thermal power plants as a lower cost alternative to traditional heavy fuels. This product has a relatively high density, very high PAH content, and forms fine bitumen droplets when added to seawater. Based on the belief that an accidental spill of this product posed a relatively high threat to benthic suspension-feeding organisms, laboratory experiments were conducted to

determine the effects of this fuel on adult *P. magellanicus* (Armstrong et al. 1999). Mortalities during 43-day chronic exposures to Orimulsion® increased with increasing fuel concentration, but were generally low with 82% survivorship at the highest concentration tested (10 mg L⁻¹). Sublethal effects were more pronounced with scope-for-growth reduced by 80% at just 0.01 mg L⁻¹. Growth reductions resulted mainly from effects on clearance rate (EC₅₀ value was between 0.01 and 0.1 mg L⁻¹), but respiration rate also increased significantly relative to controls. Further research was conducted on newer formulations of Orimulsion®, to assess manufacturer claims of reduced toxicity (Armstrong et al. 2000). Laboratory tests with *P. magellanicus* indicated that chronic exposure to Orimulsion-100 and Orimulsion-400 had no significant sublethal effects on adult sea scallops. One of the few effects observed was a significant 30% increase in clearance rate in scallops exposed to the 0.1 mg L⁻¹ treatment. Orimulsion dose levels in sea scallops were as high as 56 µg PAH g⁻¹, with no apparent growth inhibition. The large multi-ring aromatics in the bitumen are less toxic than the PAHs frequently found in crude and heavy fuel oil. The dramatic reduction in toxicity of the newer Orimulsion® formulations appears to be related to changes in the surfactant used to maintain the bitumen/water emulsion. The general lack of observed detrimental biological effects suggests that the impact on scallop stocks of a limited Orimulsion® spill will probably be minimal (Armstrong et al. 2000).

Biomagnification of organic chemicals in marine systems has been convincingly shown for only a few compounds, including methylmercury, some PCBs and PCDs, and DDT (Neff 2002). Organic mercury is presently the only trace metal (and physicochemical form) for which evidence exists to support biomagnification in the marine environment (Gray 2002). Although scallops accumulate methylmercury, they are of the second trophic level, and are expected to accumulate less methylmercury and be of less of a risk to consumers than predatory fish.

13.4 OFFSHORE OIL AND GAS OPERATIONS

The interaction between scallops and offshore oil and gas operations has been the topic of considerable research over the past decade. Much of this work is related to the rapid expansion of offshore oil and gas operation off the east coast of Canada, including areas supporting significant commercial sea scallop (*P. magellanicus*) and Icelandic scallop (*Chlamys islandica*) stocks. A major concern related to offshore oil and gas operations has been the potential environmental impacts associated with the exposure of marine organisms to operational waste discharges. Drilling wastes (spent drilling mud and well cuttings) are the primary concern during exploration and development drilling operations, while produced water recovered from the hydrocarbon bearing strata is the highest volume waste generated during production. Produced water may contain elevated concentrations of metals, nutrients, radionuclides, hydrocarbons, and trace amounts of chemical agents. Discharged drilling fluids (muds) have been the primary focus of environmental impact studies because their drift, dispersion, and dilution are generally lower than those of dissolved or buoyant discharges such as produced water.

Drilling mud formulations are highly variable containing any combination of over a thousand minor components (GESAMP 1993). Barite (BaSO_4) and bentonite (montmorillonite clay) together comprise the majority of the insoluble components of most drilling fluids (GESAMP 1993). Early studies of the fate and effects of drilling and production wastes assumed that the fine drilling mud particles and dissolved contaminants would readily dissipate resulting in low concentrations on energetic offshore banks (Neff 1987). However, it is now known that flocculation (the adhesion of smaller particles to form large particles) and surface adsorption (the adhesion of small particles to larger particles and/or droplets) are important processes in the transport of wastes from oil and gas operations (Fig. 13.1). Drilling wastes readily flocculate in seawater to form aggregates on the order of 0.5–1.5 mm in diameter with high settling velocities (Milligan and Hill 1998) such that the bulk of drilling mud discharges settle rapidly and can accumulate on the seabed (Muschenheim et al. 1995; Muschenheim and Milligan 1996). Potentially toxic metals in produced water have also been observed to transform from dissolved to particulate forms that settled rapidly. Resuspension/deposition processes in the benthic boundary layer tend to concentrate particulate wastes in suspension near the seabed before eventually being dispersed by currents and waves (Muschenheim and Milligan 1996). These observations are consistent with the conclusion that impacts from drilling operations are most severe on benthic communities (National Research Council 1983).

Early studies on drilling waste toxicity to scallops, and other species, focused on the biological effects of relatively concentrated waste suspensions ($100\text{--}1,000\text{ mg L}^{-1}$). Multi-organism studies of this type identified scallops as one of only a few organisms that appear to be sensitive to impacts from drilling wastes (Neff 1987). As a result of high waste dispersion processes in the marine environment, waste concentrations greater than about 10 mg L^{-1} are only relevant to a small region in the water column near the discharge point (Neff 1987). For a significant impact to occur at the population level, a long-term biological response would have to be caused by relatively low waste concentrations, a large portion of the population would have to be exposed, and the observed biological effects would have to be relevant to scallop survival, growth and/or reproduction. A preliminary study was conducted in 1988 to assess the potential hazard to commercial sea scallop stocks on Georges Bank of proposed oil and gas drilling activities. Chronic exposure to well cuttings containing two types of mineral oil-based drilling mud resulted in increased mortalities, cessation of reproductive and somatic tissue growth, and a decrease in condition index and metabolic reserves (Cranford and Gordon 1991). The observed impact was greater than had been observed for other bivalve filter-feeders previously tested, raising concerns about the impact on scallop stocks residing in the immediate vicinity of a drilling platform.

Cranford and Gordon (1992) developed a more ecologically relevant laboratory methodology for studying the chronic effects of different types of drilling wastes on scallops. This included the ability to conduct chronic exposures under realistic flow conditions, and the ability to expose scallops to dilute concentrations ($<10\text{ mg L}^{-1}$) of suspended drilling wastes. Exposure of *P. magellanicus* to suspended bentonite clay revealed a low tolerance to this material, with a 50% reduction in clearance rate

Figure 13.1. Major processes controlling the environmental fate (i.e., exposure of scallop stocks) of wastes from offshore oil and gas drilling and production activities.

(EC_{50}) observed at 2 mg clay L^{-1} (Cranford and Gordon 1992). Additional significant effects detected during chronic exposure to 10 mg L^{-1} bentonite included high mortality, tissue weight loss, and cessation of gonad development. The scallops immediately employed several compensatory mechanisms in an attempt to adapt to the presence of the suspended clay particles, including altering retention and selection efficiencies (Cranford and Gordon 1992) and absorption efficiency (Cranford 1995). These mechanisms allowed the scallops to maintain normal growth rates (relative to the control group) in the 2 mg L^{-1} bentonite treatment, but physiological compensations were largely ineffective at adapting to higher clay concentrations.

The high sensitivity of sea scallops to the suspended clay was not expected as only about 40% of this material is of a size that can be retained by the feeding apparatus (Cranford and Gordon 1992). Fine inorganic particles ($<10 \mu\text{m}$) have been observed to have a greater impact on gill ciliary activity in *Pecten novaezelandiae* than larger ($10\text{--}30 \mu\text{m}$) particles (Stevens 1987). Although the mechanism for this effect is unknown, the importance of gill ciliary activity in scallop feeding may explain changes in the feeding response observed by Cranford and Gordon (1992). High concentrations of attapulgite clay, also found in some drilling muds, has been shown to have an additional impact on gill ciliary functions in *P. magellanicus*. Morse et al. (1982) observed that $100\text{--}1,000 \text{ mg L}^{-1}$ suspension of attapulgite caused an “unzipping” of the ordinary filaments of the gill at the ciliary interfilamentary junctions. Clay has been used to displace harmful algal

blooms and spilled oil by spraying it over affected areas (Bragg and Yang 1995; Wood et al. 1997; Frank et al. 2000). The clay promotes the flocculation process, leading to settlement of the algae and oil on the seabed. Bay scallops (*Argopecten irradians*) exposed to clay/algal cell suspensions decreased clearance rate (Frank et al. 2000), but the effect was largely limited to concentrations greater than 100 mg L⁻¹. The effect of kaolin clay on bay scallops was not as great as was observed for *P. magellanicus* exposed to bentonite (Cranford and Gordon 1992) and it may be speculated that the presence of clay in a flocculated form reduces its impact on scallops. White (1997) showed that when bentonite was incorporated into large robust flocs in the laboratory, it no longer affected sea scallop clearance rates. However, Cranford et al. (1998) studied sea scallops exposed in the field to natural flocs and found these to be readily disrupted into component particles during feeding.

Additional studies with *P. magellanicus* were conducted to determine chronic biological effects for a wide range of operational drilling muds and their major constituents, and to identify the cause of any effect. Types of drilling muds tested are characterised as water-, oil-, or synthetic-based (WBM, OBM, and SBM, respectively) depending on the fluid component of the drilling mud. An OBM containing a "low-toxicity" (<0.5% aromatic hydrocarbon content) mineral oil had the greatest impact and was fatal to all sea scallops at 2 mg L⁻¹ within 11 days (Cranford et al. 1999). The lowest concentration tested (0.5 mg L⁻¹) caused cessation of feeding and somatic tissue growth, and resorption of gonad tissue. Three types of SBM were tested, including a low viscosity ester-based fluid and two synthetic oil-based formulations from oil and gas production sites on the Grand Banks (Hibernia) and Scotian Shelf (Sable Offshore Energy Project). All three SBMs were not lethal to *P. magellanicus* during the chronic exposures, but caused a significant reduction in tissue growth at the 1.0 mg L⁻¹ concentration (P.J. Cranford and S.L. Armsworthy, unpublished data). One test detected a significant growth effect at 0.1 mg L⁻¹. Growth reductions observed during exposure to all waste types resulted primarily from reduced energy intake through feeding (clearance rate) and digestion (absorption efficiency), but increased energy losses to respiration and excretion also contributed to reduced growth (Cranford et al. 1999).

Barite particles found in most drilling fluids have been characterised as being toxicologically inert (Neff 1987), but chronic exposures of sea scallops to barite resulted in the complete cessation of gonad growth at the lowest concentration tested (0.5 mg L⁻¹) (Cranford et al. 1999). More recent exposures show this impact to occur at concentrations as low as 0.05 mg L⁻¹ (P.J. Cranford and S.L. Armsworthy, unpublished data). SEM observations of the ctenidia of suspension-feeding bivalves have shown gill damage after exposure to barite (Barlow and Kingston 2001). It has also been suggested that barite particles cause nutritional stress by adsorption of mucus secretions, which are critical to normal feeding and digestion processes (Cranford et al. 1999).

In the past, the biological effects of drilling wastes have been grouped as being caused primarily by a combination of (1) chemical toxicity from hazardous pollutants and biodegradation products, (2) organic enrichment of sediment that may produce anoxia, and (3) physical smothering. The above studies with sea scallops show that an additional, and potentially more important cause for concern exists that could have consequences at

the population level if drilling wastes are discharged in marine areas supporting significant scallop stocks. Physical effects caused by chronic exposure to very low concentrations ($>0.05 \text{ mg L}^{-1}$) of chemically inert components found in all drilling muds (e.g., bentonite and barite) are capable of causing a significant impact on growth and reproduction, at least in *P. magellanicus*. These results may help to explain why observed impacts on benthic communities around drilling platforms tend to be greater than predicted based on the measured distribution of toxic contaminants (hydrocarbons and metals).

Cranford et al. (2003) employed a set of numerical models to evaluate the potential risk to *P. magellanicus* stocks on northeastern Georges Bank during exploratory oil and gas drilling. Georges Bank, which straddles the United States-Canadian boundary, is one of the most productive fishing banks in the North Atlantic Ocean, and supports the largest offshore scallop fishery in the world. Hydrocarbon resources on Georges Bank are believed to be extensive. Numerical models are valuable tools for evaluating the potential environmental impact of marine contaminants. These models provide a quantitative framework for integrating knowledge on the intrinsic physico-chemical properties of the different contaminants, the extrinsic processes that control their transport and fate in the environment, and information on the biological effects. The models used to predict the drilling waste zone of influence and the impact of chronic exposure on scallop growth indicated a potential for 0–48 days of growth inhibition over a 92-day drilling scenario. The wide variation in growth inhibition predictions was related primarily to specific oceanographic conditions at the site and the settling velocity of the mud (Cranford et al. 2003). Impacts were predicted to be greatest in the vertically stratified region around the side of the Bank that supports relatively small scallop stocks, but dense aggregations are found in some areas (Fig. 13.2). Impacts are expected to be more localised in the tidal front region, which has the densest scallop stocks, and minimal in the central, vertically well mixed region of Georges Bank (Fig. 13.2). The implications of such growth inhibition at the population level are not believed to be significant for a single exploration well (Cranford et al. 2003). However, the risk to scallop stocks would be much greater during oil and gas development operations where multiple wells are drilled almost continuously, sometimes at multiple sites, over many years. Drilling for oil and gas on Georges Bank is currently prohibited by legislation in both Canada and the US.

13.5 SCALLOPS AS SENTINEL ORGANISMS

The strategy for monitoring the health of the oceans is evolving from a focus on chemical contaminant distributions to pollution assessments that emphasise the measurement of meaningful biological responses to available contaminants (Bayne et al. 1988; Stagg 1998). Information obtained on contaminant concentrations during field monitoring programs is greatly enhanced by the availability of biological effects data and it has been suggested that the analysis of chemical contaminants is only necessary if a biological effect is detected (e.g., Gray 1999). An advantage of biological effects monitoring programs is that they can indicate the presence of a contaminant that was not previously identified as being of concern. Data on biological responses to contaminants have often come from laboratory studies conducted to reflect acute or relatively short-term

Figure 13.2. Potential growth inhibition (PGI) predicted at model application sites on Georges Bank during drilling of a typical exploratory oil and gas well, in relation to the distribution of *P. magellanicus* stocks and oceanographic zones. PGI estimates (vertical bars) are shown as the percent of time that tissue growth is predicted to be inhibited by the effects of drilling waste discharges. PGI estimates are averaged over a radius of 10 km from the discharge point during the first 62 days of drilling activities. Stock distributions were calculated based on average catch statistics from 1993–1997. The net direction of the drilling waste plume at each site during summer is indicated by the arrows. Adapted from Cranford et al. (2003).

chronic responses to highly contaminated conditions. It is more important to know the effects of much longer-term exposures to very small, and often fluctuating quantities of chemicals. Extrapolation of laboratory results to natural conditions through numerical modelling or environmental risk assessment approaches contain, and must account for, uncertainties regarding prediction of a wide range of environmental processes affecting contaminant availability to organisms (e.g., adsorption, desorption, vertical flux,

resuspension, dissolution, and degradation). Although it is important to continue to quantify exposure-response relationships for different contaminants under controlled laboratory conditions for predictive purposes, the long-term monitoring of biological responses to ambient contaminant concentrations would help to reduce uncertainty by directly looking for impacts of xenobiotic substances on populations.

A number of prerequisites have been developed for the selection of biological indicators of contaminant exposure and bioavailability. The selected indicator species should be sedentary, abundant, widely distributed, long-lived, easily obtained, of sufficient size for tissue analysis, and must accumulate the contaminant with a high concentration factor. Based on these criteria, mussels and oysters have been widely employed for monitoring coastal contaminant distributions, and there is now a good appreciation of what constitutes low to high contaminant levels in their tissues. Scallops are also well suited as contaminant indicators based on these criteria, but they have not been widely employed in coastal monitoring programs. Some exceptions include the use of *A. colbecki* to monitor trace metal contamination around Antarctica (Berkman and Nigro 1992), and *P. maximus* for estimating the degree of coastal PAH pollution in France (Friocourt et al. 1985). For an organism to be of use for assessing and monitoring both environmental contamination and subsequent biological effects, the indicator species should be susceptible and sensitive to the toxic and/or physical effects of a wide range of contaminants. It is also highly desirable if the target organism is economically important to the study area. Scallops appear well suited to the role as a sentinel species for contaminant and biological effects monitoring owing to the combination of being a strong accumulator of many contaminants and exhibiting a relatively high sensitivity to the toxic and physical effects of many contaminants (this review). They are also resident in commercial quantities in deep shelf waters where more traditional bioindicator species would require transplantation.

An integrated approach to environmental effects monitoring, known as the exposure-dose-response triad has been developed that is based on weight-of-evidence from the results of caged bivalve studies (Salazar and Salazar 1998). This method combines measurements of environmental contaminant concentrations in water and/or sediment (exposure) with measurements of bioaccumulation (dose), and biological responses. It is important to measure both exposure and dose as the response may be related primarily to the dose (trace organics), or to the exposure (inorganic metals). No direct relationships exist between total bioaccumulation of metals and toxicity due to the physico-chemical forms of sequestration (Berthet et al. 1992). A wide range of potentially relevant biological variables (bioindicators) are available for use in monitoring programs, with some indicating that the organism was exposed to a pollutant, and others showing the biological consequence of contamination. The most useful types of measures provide an early warning of the onset of toxicity and/or provide information that is directly relevant to effects at the population to ecosystem levels. The latter include measures of effects on growth, reproductive potential, and survival. Such effects are clearly relevant to population sustainability as they determine the individual's ability to contribute to the population gene pool.

Scallop populations have been employed on several occasions in experimental biological effects monitoring programs. Commercial stocks of *P. maximus* and *Aequipecten opercularis* were employed for detecting insecticide exposure in the Bay of Brest area of France (Bocquene 1997), and *Euvola (Pecten) ziczac* populations were sampled for the same purpose at two sites in Bermuda (Owen et al. 2002). Both studies used acetylcholinesterase activity (AChE) as a biomarker of organophosphorus and carbamate pesticide exposure. AChE activity was shown to be substantially inhibited at environmentally relevant concentrations (Owen et al. 2002). Bocquene (1997) found no evidence of AChE inhibition in adductor muscle extracts that would indicate the presence of insecticide contaminants, but Owen et al. (2002) showed seasonal AChE inhibition in scallop hemolymph that appears to reflect contamination. The hemolymph assay was shown to be of greater value for biomarker applications than the muscle extract method (Owen et al. 2002). Regoli et al. (1997, 1998) proposed using lysosomal and antioxidant responses in *A. colbecki* as an early warning tool for detecting environmental disturbance in the Antarctic environment. Although laboratory studies by these authors demonstrated significant lysosomal and antioxidant responses to copper and mercury exposure, only a limited effect was observed in scallops residing in cages in a bay receiving discharges from the Italian Antarctic Base (Regoli et al. 1998). It was subsequently concluded that the Base should not have a major impact on benthic communities in the bay. It should be noted that the sensitivity of the Antarctic scallop biomarkers to detect an impact in the field has not been established as only a single, and extremely high concentration was used to document the response to the different metals.

In response to laboratory observations of the high sensitivity of sea scallop growth and physiological responses to very dilute concentrations of operational drilling wastes (Cranford and Gordon 1991, 1992; Cranford et al. 1999), two biological effects monitoring tools were developed using scallops as sentinel organisms. These tools were tested at 80 m depth at the Hibernia oil production site on the Grand Banks off Newfoundland, Canada. The first approach is based on the *in situ* sediment trap method of Cranford and Hargrave (1994) for continuously and autonomously monitoring feeding and digestion responses of bivalve filter feeders. In this method, sediment traps (HABITRAPs) are used to quantitatively collect biodeposits at regular programmed intervals from a cohort of scallops feeding under natural conditions in the field (Fig. 13.3). This method has been used extensively for measuring scallop functional responses to natural environmental variations over different time scales (Cranford and Hargrave 1994; Cranford et al. 1998; Cranford and Hill 1999). The rationale for applying this method as a monitoring tool is that food utilisation by bivalves is highly sensitive to the presence of many contaminants, including dilute concentrations of drilling wastes (Axiak and George 1987; Widdows et al. 1987; Cranford et al. 1999). The provision of biological response measurements over short time intervals (days) permits the identification of waste release

Figure 13.3. Biological effects monitoring tools using scallops as sentinel organisms for measuring effects of offshore oil and gas drilling operations. Cages (top) and sediment traps (bottom) were deployed in 80 m of water near the Hibernia platform off Newfoundland. The cage is placed on the seabed using an acoustic release (top left photo) and is recovered after the subsurface floats are released by a timed mechanism. *Placopecten magellanicus*, *Chlamys islandica* and *Mytilus edulis* were held separately in 'pocket' nets (top right) behind a predator mesh on each wing of the cage (top left). Time-series sediment traps called HABITRAPs (bottom left) were deployed near the seabed with and without *C. islandica* (bottom right) to monitor scallop biodeposition and sedimentation rates over 3-day intervals for a total of 72 days (photos by the author).

practices (e.g., rate and type of waste discharge) having the greatest impact on scallops. The HABITRAP approach is unique in that sequential sampling is automated over user defined time scales, while providing information on all three elements of the exposure-dose-response triad. Measurement of contaminants or tracers collected in the sediment traps define the exposure, analysis of contaminants in scallop tissues at the end of the exposure defines the dose, and the time series of feeding, absorption, and/or biodeposition rate defines the response.

A second tool was developed and tested for biological effects monitoring at offshore oil and gas operations that consisted of a series of *in situ* moorings containing caged *C. islandica*, *P. magellanicus* and *M. edulis* (Fig. 13.3). Six identical moorings were placed on the seabed between 0.5 to 6 km from the Hibernia platform. Data on lethal and sublethal effects and hydrocarbon body burdens were collected to help define the spatial extent of benthic impacts from oil drilling activities. Changes in survivorship, somatic and reproductive growth, and condition index were selected as biomonitoring parameters because they are relatively easy and inexpensive to measure (i.e., practical) and are relevant to population dynamics. Mortality (<10%) of scallops was low during the study, and no significant difference in mean tissue dry weight (gonad, adductor, digestive, and total) was detected between the six sites at the end of the three-month exposure (P.J. Cranford and S.L. Armsworthy, unpublished data). HABITRAP data showed that drilling wastes (barium) were only in suspension for a brief period during the study and that concentrations were below the threshold known to impact feeding and growth rates.

With many countries presently attempting to establish ecosystem-based approaches to the management of marine resources, the objectives and methodologies of current environmental and fisheries surveillance programs need to be re-evaluated. Any assessment of the cumulative effect of all activities potentially impacting an environment that is prone to large natural variations is a formidable task. A pragmatic approach to cumulative effects monitoring may be to integrate environmental quality and fisheries management programs based, in part, on a similar suite of core biomonitoring parameters. Routine stock assessments measure changes in scallop population dynamics (e.g., abundance, distribution, age structure, growth rate and reproductive effort) that can be related directly to the fishery and to other human-induced stresses and natural variations. For regions having significant scallop resources and which already conduct stock assessments, a cumulative effects monitoring approach could be implemented by conducting additional diagnostic bioassay and biomarker tests (including contaminant bioaccumulations in scallops) to identify probable causes for observed changes in wild scallop populations. Interpretation of data from such a biological monitoring program would have to be based on obtaining a thorough understanding of contaminant accumulation dynamics and contaminant-response relationships for the target species.

ACKNOWLEDGMENTS

I am grateful to B.T. Hargrave and S.L. Armsworthy for providing valuable comments on the manuscript. Unpublished results are presented from studies funded by Fisheries and Oceans Canada, and the Program for Energy Research and Development.

Chapter 14

Dynamics, Assessment and Management of Exploited Natural Populations

J.M. (Lobo) Orensanz, Ana M. Parma, Teresa Turk and Juan Valero

14.1 INTRODUCTION

Since the first edition of this book, published a decade ago, there has been substantial progress in our understanding of scallop population dynamics. Most significant are new results on the structure of metapopulations, the mechanisms involved in larval retention/dispersal, and the relationship between aggregate stock abundance and subsequent settlement/recruitment. There has been a renewed interest in the fishing process, particularly regarding the behaviour of fishers and fleets. Methods used for estimating abundance have paid increasing attention to spatial structure, including both design-based approaches (e.g., adaptive sampling) and model-based methods (e.g., geostatistics). Yet, among the subjects covered in this chapter, it is perhaps in the management arena where changes have been most radical. This is in part a result of the debates over sustainability and governance originating in the so-called “World Fishing Crisis”. Management of benthic resources has begun to emerge with an identity of its own, differentiated from conventional (finfish) management by a new and growing emphasis on spatially explicit approaches, and on the role of stakeholders in co-management.

In revising this chapter we have tried to do justice to these fundamental developments, which required a complete rewriting of all sections. We have virtually dropped the entire section on the estimation of growth and mortality parameters, which is covered at length in the first edition. The readers are referred to other chapters of this book for new developments on these topics.

14.2 SPATIAL SCALES AND SCALE-SPECIFIC PROCESSES

All scallop stocks are structured as “metapopulations”¹ in which subpopulations of sedentary² post-larval individuals are connected with each other through the dispersal of pelagic larvae. The metapopulation is a useful conceptual framework for the analysis and management of benthic fisheries in general, as indicated by trends in the literature over the last decade (Orensanz and Jamieson 1998). This emerging paradigm emphasises the spatial structure of benthic stocks, in contrast with the fin-fishery-inspired approaches that once used to dominate the scene. Emphasis on spatial structure brings with it the need to identify appropriate spatial scales for the observation, analysis and management of

exploited scallop stocks. Here we adopt the hierarchy of spatial scales presented by Orensanz and Jamieson (1998).

Megascale, at which there is detectable geographic genetic differentiation between populations.

Macroscale (large scale): metapopulations composed of spatially disjoint subpopulations connected through the dispersal of pelagic larvae.

Mesoscale (intermediate scale): subpopulations within a metapopulation. This is typically the scale of fishing *beds*, usual units in traditional stock assessment.

Microscale (small scale): neighbourhoods of individuals, within which a certain interaction between the individual and its environment is effective.

Nanoscale, characterised by processes taking place at low Reynolds numbers.

Relevant processes taking place at each of these scales are summarised in Table 14.1. In this review, we will emphasise macro, meso and microscale phenomena:

Macroscale: source-sink (SS) dynamics in metapopulations. The pattern of connectivity³ between components of a metapopulation is the scaffolding underlying SS dynamics, ranging from the ideal model of a well mixed larval pool (maximal connectivity) at one extreme, to a collection of closed self-sustaining populations (minimal connectivity) at the other. Connectivity is never symmetrical: larval flows between two subpopulations will always be stronger in one direction. Maximum asymmetry is found in non-reproductive *pseudo-populations* (absolute sinks), which depend exclusively on imported recruits and do not contribute larvae to other populations.

Mesoscale: contraction-expansion (CE) dynamics in subpopulations. The mesoscale is the domain of traditional fisheries models, in which emphasis is on change in population size over time. In recent years, there has been increasing interest in the CEs of geographic range that accompanies change in aggregate⁴ abundance. In fishes and other mobile organisms CEs of subpopulations are mediated by the active displacements of individual organisms along environmental gradients; changes in the range occupied by a subpopulation happen within the time-frame of a generation and can be rapid. In scallops and other sedentary invertebrates, CEs are mediated mostly by the advection of larvae; changes in the range occupied by a subpopulation involve more than one generation and can be slow and noisy.

Microscale: Density-dependent (DD) processes within neighbourhoods. The DD mechanisms that control recruitment⁵ to benthic stocks, whether compensatory or depensatory, always have small operational spatial scales. The effects of those processes on recruitment, however, may occur at varying spatial scales depending on whether DD occurs before or after dispersal (Botsford and Hobbs 1995). *Pre-dispersal* DD processes includes reduction of growth and fecundity at high density due to competition for a limited food supply, and the DD of fertilisation rate in broadcast spawners. Typical *post-dispersal* DD processes involve various forms of inhibition of settlement or recruitment

by high densities of local residents, as well as gregarious settlement of larvae in the neighbourhood of adult conspecifics.

The scales introduced above are defined in terms of processes of interest, not of dimensional bounds. Roughly, in the case of scallops, typical metric scales are in the order of mm for the nanoscale, cm to m for the microscale, km for the mesoscale, tens to hundreds of km for the macroscale, and thousands of km for the megascale. We use the words “site”, “bed” and “ground” for, loosely, regions commensurate with micro, meso and macroscale processes, respectively. A “fishing ground” is typically occupied by a metapopulation. “Beds” (equivalent to the Spanish “bancos”) within a ground are more or less discrete patches with high (fishable) density, generally occupied by a subpopulation. Scallop fishing grounds and beds are identified by name in most scallop fisheries. Sites are small partitions of the bottom (in the order of tens of m²), commensurate with the typical experimental sites of ecologists.

In traditional finfish fishery models, there is no explicit consideration of spatial structure or spatial scales. Basic models of the dynamics of exploited stocks are constructed around two tenets (Caddy 1975):

The unit stock concept: A “unit stock” is defined as a self-sustaining unit of population, closed to immigration or to recruits originated by other stocks. In its more general form, this concept makes no explicit allowance for spatial distribution of abundance and fishing effort; fishing mortality is assumed to be proportional to fishing effort.

The dynamic pool assumption: Real populations are contagiously distributed, and fishing effort tends to concentrate on dense areas. Active dispersal by the fish is invoked to spread the local effects of fishing events (“redistribution”), so that locally depleted areas are replenished by immigration. Without this assumption “catchability” would be unevenly distributed, *CPUE* (“catch per unit of effort”) would not be proportional to abundance, and fishing mortality would not be proportional to fishing effort.

It is immediately obvious that the very nature of scallop stocks is at odds with these basic notions:

The unit stock assumption rarely holds. Subpopulations in a metapopulation are generally “open” to recruitment, and connectivity between subpopulations is never symmetrical.

The dynamic pool assumption never holds. Fishing intensity tends to match the distribution of density. Adult scallops, being sedentary, do not “redistribute” themselves following a spatially localised fishing event. Although scallops are able to move, the scale of their displacements is very small relative to the scale of the fishing process. Fishing mortality varies spatially; the chances of being fished vary amongst individuals, and are related to density in their neighbourhoods. The relations between *CPUE* and abundance, and between fishing mortality and effort, depart from simple proportionality (Section 14.5).

Table 14.1

A hierarchy of relevant spatial scales, typical methods of pattern description, and processes commensurate with each scale. In this overview we emphasise macro, meso and microscale phenomena.

Spatial scale	Definition	Typical method of pattern observation or description	Examples of processes commensurate with scale
MEGA	Zoogeographic range of an Artenkreis or Rassenkreis, respectively collections of closely related species or genetically differentiable stocks	Large-scale maps	Speciation
MACRO (= large)	Metapopulations, or “populations of populations”	GIS	Dispersal of pelagic larvae among populations
MESO (= intermediate)	Populations (or subpopulations) within a metapopulation. Typically the scale of individual fishing beds	Geostatistical methods, GAMS	Tactical decisions by fishers
MICRO (= small)	Neighbourhoods of individuals, the pertinent scale to describe interactions taking place in dense “patches”. The “neighbourhood” is a region within which a certain interaction between the individual and its environment is effective	Spatial point process methods; concentration profiles	Competition Fertilisation rate Sensorial perception
NANO	Processes taking place at low Reynolds numbers (predominance of viscous over inertial forces)	Microphotography; flow chambers	Particle collection in the feeding structures of suspensivores. Interaction between eggs and sperm in broadcast spawners. Settlement of pelagic larvae in the boundary layer

Throughout this chapter we discuss each subject (structure, dynamics, the fishing process, assessment and management) with reference to the pertinent spatial scale. Whenever we refer to aggregate meta- or subpopulations, this is made explicit.

14.3 POPULATION STRUCTURE AND DYNAMICS

14.3.1 Aggregate Stocks

The primary factors tuning year-class-strength are those that affect advection and survival of pelagic larvae. These factors pertain largely to oceanographic conditions. Thus, it is natural that research on modulation of year-class-strength and the search for signs of climatic forcing should focus on abundance indices aggregated at relatively large spatial scales. Usually, the longest time series of data available correspond to the catches. These are limited because the contribution of individual year classes is blurred by the dynamics of the stock and the fishing process (recruitment fisheries provide some exceptions; Section 14.6.2.3). Yet, catch statistics are informative about the broadest patterns of fluctuation in population abundance. We address this subject in Section 14.3.1.1, below. In Section 14.3.1.2, we consider empirical evidence (mostly of correlational nature) about the influence of climate on larval availability and recruitment. The transition between these two stages – pelagic larvae and recruits – is, however, modulated by factors other than larval availability. A rich literature has accumulated over the last decade on the relative importance of pre- vs. post-settlement processes in regulating recruitment; the “recruitment limitation hypothesis”, claiming that recruitment is limited by larval availability, has been scrutinised. We present empirical evidence about correlation between abundance of different life-history stages in Section 14.3.1.3. Finally, in Section 14.3.1.4 we discuss the elusive relationship between aggregate spawning stock and recruitment. In the case of scallop-like organisms the recruitment process involves a sequence of processes with different operating spatial scales, which are considered in Sections 14.3.2–14.3.4.

14.3.1.1 Patterns of fluctuation

Caddy and Gulland (1983) classified harvested stocks in four groups, according to their pattern of fluctuation:

(1) *Steady stocks* remain at about the same level year after year, with variations that generally do not exceed 20–30% of the long-term average. Some boreal or arctic populations of long-lived scallop species may fall into this group. Golikov and Scarlato (1970) characterised the *Patinopecten yessoensis* population from Posjet Bay as “stationary”, although they did not give quantitative information on long-term population size or year-class strength. Density in a bed of *Chlamys islandica* studied by Vahl (1982) in North Norway showed insignificant change over 9 years.

(2) *Cyclical stocks* show a repeated alternation of periods of high and low abundance. Although strict periodic behaviour is possible, fluctuations with uneven period (quasi-periodic) are more common. Cycles can result from predator-prey interactions, nonlinear renewal, or fluctuations in an external (climatic) variable modulating year-class strength. The most dramatic scallop cycle was that documented by Caddy (1979a) for a *Placopecten* stock of the Bay of Fundy (Nova Scotia). Annual landings from the Digby inshore fishery fluctuated cyclically between 1922 and 1971. Correlograms for catch, fleet size and inshore catch per boat showed pronounced maxima at lags of 8–10 years, suggesting an underlying periodicity of 9 years. Annual catch and fleet size were strongly cross-correlated and in phase. Caddy (1979a) considered several alternative hypotheses to explain the cycle, and concluded that climatic forcing (perhaps fine-tuned by density dependence and harvesting) was the most consistent with the pattern. Inshore catches of *Placopecten* from Maine between 1897–1980 also show quasi-cyclic fluctuations (Dow 1969). Average biomass and year class strength of *Aequipecten tehuelchus* in the San Roman bed (Patagonia) showed a 5-year cycle over the period 1969–1983 (Orensanz 1986). It was produced by three exceptionally strong year-classes (1970, 1975, 1980), and may have resulted, to some extent, from density-dependent settlement (Section 14.5).

(3) *Irregular stocks* fluctuate greatly from year to year without any clear pattern, as is frequently the case when recruitment is strongly dependent on hydrographic conditions. Irregular stocks are exemplified by the Georges Bank and St. Pierre Bank stocks of *Placopecten magellanicus* (Mohn et al. 1988; Naidu and Anderson 1984).

(4) *Spasmodic stocks* show irregular pulses of high abundance followed by periods of scarcity or collapse. Many scallop stocks fit this type. Exceptional environmental conditions underlie spasmodic pulses in three well-documented and dramatic cases:

i) The *Patinopecten yessoensis* stock of Mutsu Bay, Japan (Yamamoto 1964; Yamamoto in Imai 1971; Aoyama 1989; Anonymous 1990), before 1970. Kishigami (cited by Yamamoto in Imai 1971) informed of pulses in 1861–62, the late 1860's and the late 1880's. In the present century, there were pulses in 1909–1910, 1926–1929; 1950, 1959, and 1970–1973. Yamamoto (1960, 1964) attributed them to “abnormal fecundity” due to exceptionally high spat survival. Under normal conditions, plankton (including scallop larvae) is concentrated by eddies (Section 14.3.1.1) in areas 30–70 m deep, that are not the normal habitat of the scallop. Flow in eddies stop during the summer, producing stratification and anoxic conditions near the bottom, and mass mortality of scallop spat. In some years, however, stratification does not occur, anoxic conditions do not develop, and sinking plankton does not accumulate. Survival of spat is then high, resulting in the “abnormal fecundity” phenomenon (Yamamoto 1964; Imai 1971).

ii) In the *Amusium pleuronectes* stock of Shark Bay (Western Australia), a large recruitment in 1990 resulted in spawning stocks in 1991–1992 about ten times larger than previous levels (Caputi et al. 1998). Yet, subsequent recruitments failed due to the Leeuwin Current strength (Joll and Caputi 1995; Caputi et al. 1998; Section 14.3.1.2).

iii) The population explosions of *Argopecten purpuratus* in Perú and northern Chile following El Niño events (Wolff 1987; Navarro-Piquimil et al. 1991; Wolff and Mendo 2000). Following the 1983 event, stock size exceeded more than 60 times that of “normal” years. Factors involved in these pulses include increased individual growth rate, increased larval survival and/or intensified spawning activity associated with temperature 6–8°C higher than normal, and higher survival due to mortality or emigration of predators and competitors.

14.3.1.2 Climatic forcing

The most dramatic examples of climatic forcing are provided by some spasmodic populations, discussed above. Climatic forcing is most often revealed by cross-correlation between year-class strength and environmental variables. Even in the absence of long time series of data, geographic coherence in recruitment (large-scale spatial correlation in year-class-strength) is often a signature of climatic forcing, as this is in most cases the only large-scale factor that can synchronise the pattern. Orensanz (1986) and Ciocco and Aloia (1991) reported that year classes of the tehuelche scallop (*Aequipecten tehuelchus*) are weak or strong across the entire metapopulation of San José Gulf, pointing to large-scale climatic forcing as the likely cause.

Climate drives scallop recruitment, and consequently the dynamics of scallop populations, in two main ways:

(1) Variation in reproductive schedules: Like other sedentary organisms (and unlike pelagic or demersal fishes) scallops are not able to migrate tracking their environmental preferences. While highly mobile organisms are able to adjust the location of their spawning grounds in response to year-to-year variation in oceanographic conditions, scallops respond only by “tuning” their schedule of reproductive events (timing and magnitude), eventually resulting in the failure of spawning in a given season. Failed spawning has been well documented for *Patinopecten yessoensis* (Yamamoto 1964), and for *Pecten maximus* in the Bay of St. Brieuc (France), the latter following an unusually cold year. The impact of spawning failures is most significant in the case of short-lived semelparous species, as illustrated by the collapse of the *Argopecten gibbus* fishery off Cape Canaveral (east Florida) in 1985 (Moyer and Blake 1986). This population apparently has two spawning periods: a main one in spring (average size of spawning scallops small), and a smaller one in the fall (average size of spawning scallops large). In the autumn of 1984, however, no reproduction was observed. This resulted in a small spawning population of small scallops in the next spring. The main spawning stock was composed of the few large scallops that over-wintered; the fall spawning, although small, may be very important for the persistence of this stock.

A sudden change in temperature is the major trigger for spawning in scallops and other broadcast spawners with external fertilisation. This points towards strong selective pressure favouring synchrony of reproductive events. There are three well-documented cases in which high abundance or larval settlement apparently results from temperature-mediated synchrony in spawning:

i) Successful spawning of *Patinopecten yessoensis* in Mutsu Bay (Japan) requires a sudden rise in temperature (to a minimum of 8–8.5°C) within the spawning season, between March and May (Yamamoto 1964). Yamamoto (1964) investigated different hypotheses to explain a series of exceptional sets (1948, 1952, 1954, 1957 and 1960). High abundance of pelagic larvae was observed in four years (1948, 1952, 1956 and 1957), in all of which temperature rose abruptly in April.

ii) In *Pecten maximus* from Brittany, reproductive success increases with spawning synchrony. When temperature fluctuates near the spawning trigger (16°C), partial asynchronous spawning prevails, and relative larval density is low (Boucher 1985).

iii) In *Placopecten magellanicus* of the Gulf of St. Lawrence (Canada), an 8-yr study by Bonardelli et al. (1996) indicated that spawning was not controlled by critical temperature or cumulative degree-days thresholds, but was strongly associated with sudden changes in temperature caused by downwelling of warm surface water. Delay between locations coincided with the propagation rate of downwelling events. Strong cohorts (1988, 1990) resulted from abrupt, synchronous spawning (Claereboudt and Himmelman 1996, discussed by Bonardelli et al. 1996). Weakest cohorts (1986, 1989) resulted from seasons in which multiple (asynchronous) spawning prevailed. A relationship between year-class strength and spawning synchrony had been suggested before for other populations of the same species by Dickie (1955) and Langton et al. (1987).

Although temperature is the variable most often invoked, other factors may be significant as well in controlling the timing of spawning events, e.g., phytoplankton (Arsenault and Himmelman 1998) and lunar or tidal phases (Parsons et al. 1992). Bonardelli et al. (1996), however, found no indication of these factors being triggers for spawning in *Placopecten magellanicus* from the Gulf of St. Lawrence (Canada).

(2) Variation in larval advection: Dickie (1955) found that abundance and recruitment in the Digby area (Bay of Fundy) stock of *Placopecten magellanicus* was positively correlated with water temperature 6 years before. Spawning in the Digby area begins by mid July, peaks in August-September, and terminates by late September. Lagged cross-correlation between year-class strength and water temperature was highest for the month of October, pointing to mechanisms operating once spawning was over and larvae were in the plankton. Dickie proposed a composite hypothesis involving temperature-mediated rate of larval development and larval advection. Low temperatures are indicative of great exchange between the Bay of Fundy and outside water masses. Slower larval development and increased duration of larval stages in cold years would result in a high proportion of larvae being advected off the bay. In contrast, high temperatures would lead to higher retention of larvae in the vicinity of the parental beds, good settlement, and high recruitment six years later. Experimental studies (MacDonald 1988; Tettelbach and Rhodes 1981) have confirmed that survival of scallop larvae does not decrease (and often increases) at low temperatures (within normal range), but that development rate is depressed. Caddy (1979a) later expanded Dickie's time series to 50 years, and found significant cross-correlation between temperature and CPUE with lags of up to 5 years.

The cyclic pattern that he found (Section 14.3.1.1) indicates that long-period tidal oscillations might be responsible for fluctuations in both temperature and (directly or indirectly) recruitment. In the saucer scallop (*Amusium balloti*) of Shark Bay (Western Australia) the strength of recruitment is significantly and negatively correlated with the strength of the offshore Leeuwin Current (which is under the influence of the ENSO events) during the spawning season (Joll and Caputi 1995). Proximate mechanisms possibly involved are reduced spawning (discussed above), and/or flushing of larvae away from suitable grounds.

14.3.1.3 Correlation between consecutive life-history stages

Stages involved in the recruitment process include spawning, fertilisation, larval survival and dispersal, settlement, and post-settlement growth and survival (Hancock 1976). Correlation between consecutive stages is informative for the identification of recruitment bottlenecks. Strong correlation between larval availability in the water column and recruitment, for example may give support to the “recruitment limitation hypothesis” (Ólafsson et al. 1994), stressing the importance of larval supply to explain recruitment success. Alternatively, lack of correlation may point to the significance of processes affecting the settlement/post-settlement stages, or it may simply reflect substantial process and/or observation errors, or a mismatch between the operating spatial scales of process and observation. Indeed, a cautionary note is needed here. Larval availability may appear to be “limiting” or not depending on the scale of observation. Suppose, as a simplification, that density of conspecifics was a major factor controlling post-dispersal survival (pure post-dispersal compensation; Section 14.3.4.3). A bed is usually a collection of sites, some “saturated” by residents and/or settlers, others not (Sections 14.3.1.4 and 14.3.4). Observations from saturated sites would stress the significance of post-settlement survival. Yet, at the larger scale of the bed or ground recruitment could still increase with increased larval availability, provided that many unsaturated sites were left. This would highlight the relative importance of larval availability (the “recruitment limitation hypothesis”). The two perspectives are relevant, but must be properly specified. The astounding increase in recruitment in Mutsu Bay that accompanied the development of aquaculture and consequent stabilisation of an abundant spawning stock (Section 14.3.1.4) may point to the existence of unsaturated sites (even at high aggregate levels abundance). In the San José Gulf metapopulation of tehuelche scallops, large-scale forcing of settlement/recruitment was detected in lightly-populated beds as well as in beds that showed unequivocal signs of overcompensation (Orensanz 1986).

Long-term studies conducted in Brittany (France) by the *Centre Oceanologique de Bretagne* on *Pecten maximus* (Buestel et al. 1979; Boucher 1985), under the framework of the “*Programme National sur le Déterminisme du Recrutement*” (Thouzeau 1987, 1991a), and in Mutsu Bay (Japan) by the *Aquaculture Center of the Aomori Prefecture* on *Patinopecten yessoensis* (Ventilla 1982; Aoyama 1989), are unique in having addressed simultaneously the multiple stages involved in scallop recruitment. These programs combined observations of gonadal condition, abundance of pelagic larvae, and settlement

on artificial collectors. In Brittany (Boucher 1985) correspondence was (i) weak between spawning intensity and larval density, (ii) good between larval density and settlement (as has been also observed in *Patinopecten yessoensis*; Kanno (1970) cited by Ventilla (1982), his fig. 12), and (iii) very good between settlement and recruitment to age class 2+. Correspondence between spawning activity and density of larvae of *Pecten maximus* in the plankton improved when precocious and late cohorts were discriminated. The spawning schedule (rather than larval transport, starvation or predators) seemed to be the primary factor determining differences in larval density between cohorts and year-classes in Brittany. For a given amount of sexual products, according to Boucher (1985), late spawning bursts produce more larvae than early ones. Interestingly, Bonardelli et al. (1996) observed that synchronous spawning occurring in late August, coinciding with high mean gonadal mass, gave rise to strong cohorts in *Placopecten magellanicus* in the Gulf of St. Lawrence (Canada).

Good correlation between settlement indices (e.g., from spat collectors) and pre-recruits or recruits has been reported in other cases as well, e.g., in *Pecten fumatus* from Port Phillip Bay (southeastern Australia) (Sause et al. 1987), and *Aequipecten opercularis* and *Pecten maximus* from Scotland (Fraser 1991).

Not surprisingly, significant lagged cross-correlation between pre-recruits and recruits has been observed on many occasions (e.g., Coleman et al. 1988), allowing short-term forecasts that are valuable to managers and fishers. This is particularly so in the case of "recruitment fisheries", where the abundance of pre-recruits is strongly correlated with the catch in the following year. Examples have been presented by Joll and Caputi (1995), for *Amusium balloti* of Western Australia, and by Thouzeau (1991b) for the *Pecten maximus* stock of the Bay of St. Brieuc (France). The most impressive example is the correlation between seed input and scallop production in Japan (Ito 1991, f.15). Beyond their practical significance, these "mega-experiments" strengthen the notion that many sites within scallop beds are well below carrying capacity under natural conditions. These observations, however, are not conclusive with respect to the relative significance of pre- vs. post-settlement processes under natural conditions, as scallop production involves both sowing and control of predators and competitors.

14.3.1.4 The relation between aggregate spawning stock and settlement/recruitment

The relation between aggregate stock size and recruitment is the result of diverse processes, decoupled in their temporal and spatial scales. Spawning and larval survival depend on large-scale conditions (climate, spawning stock size), while receptiveness of sites to settlement depends on local (small-scale) conditions. Recruitment to one bed is affected by conditions prevailing in other (eventually distant) beds. Young et al. (1989) captured this notion clearly: "*the number of larvae competent to settle is related to the parent stock, but the number actually settling is dependent on unknown physical or biological factors at the settlement site*". Decoupling of spatial scales relevant to the different life history stages involved in the recruitment process implies that, in principle, aggregate stock-recruitment relationships (e.g., as described by the Beverton-Holt and Ricker stock-recruitment models) should not be expected in any subpopulation open to

settlers originated in other subpopulations. At that spatial scale, lack of pattern is something to be expected *a priori*, not to be explained *a posteriori*.

Good settlement may occur occasionally at times when the spawning stock is at a very low abundance (Joll 1989; Román 1991; Naidu 1991, p. 869; Kenchington and Lundy 1996, p. 3; Ciocco and Monsalve 1999a, 1999b). Observation of these compelling cases, in isolation, may give a false impression of either large-scale over-compensation (strong negative relation) or no relation between spawning stock and recruitment. On average, however, evidence suggests that pulses of recruitment are more frequent (in time and/or space) when spawning stock is higher. There is a handful of informative cases in which observations on recruitment were made in assumably self-sustaining stocks. These fall into three groups:

1) Recruitment after spawning biomass was dramatically enhanced by massive aquaculture:

i) In Mutsu Bay (Japan), before the 1970s, average settlement of *Patinopecten yessoensis* per standard collector was in the order of a few hundred spat (Ventilla 1982, his fig. 12; Aoyama 1989). After scallop aquaculture multiplied and stabilised the size of the spawning stock, settlement rose to more than 10,000 spat per collector (improved forecasting of settlement peaks also contributed). After years of bottom seeding in Sarutsu, the practice was stopped during 1980–1985 because of the high availability of wild scallops from natural recruitment (Ito 1991, p. 1044).

ii) Chilean scallop (*Argopecten purpuratus*) harvests from natural populations sharply peaked at ca. 5,000 t in 1984, following the 1982/83 ENSO event (Navarro-Piquimil et al. 1991); stocks were overfished afterwards, and the fishery was subsequently closed in 1988 (Stotz and González 1997a). During the 1990s a parcel of 1,900 ha of seabed in Tongoy Bay (North-Central Chile) was destined to scallop aquaculture. Production rose fast, soon reaching an all-time maximum of ca. 11,000 t in 1994. During the same period, average density in a TURF granted to an adjacent fishing village rose gradually six-fold over a three-year period. While this may reflect in part the positive effects of co-management (Section 14.6.3.4), increased recruitment from the new, stable adjacent source is likely to have had a major effect.

iii) Recovery of Jicon scallop (*Chlamys farreri*) stocks in Liaoning and Shandong Provinces (China) has been attributed to the development of raft aquaculture for that species (Luo 1991).

2) Recruitment after spawning biomass declined to very low levels due to either natural causes or overfishing:

i) The age structure of the tehuelche scallop (*Aequipecten tehuelchus*) population of San Matías Gulf (Argentina) indicates that recruitment was stable before the stocks were overfished during 1969–1971, but turned to spasmodic (two pulses of recruitment over a 30-year period) afterwards (Ciocco et al., Chapter 26).

ii) Dredge (1988) observed weak recruitment of *Amusium japonicum balloti* in depleted beds of Queensland.

iii) Young and Martin (1989) noticed that recruitment failure of most beds of *Pecten fumatus* in southern Australia occurred after a period of commercial fishing (ending by the mid-1980s) and suggested that a certain minimum adult density was required to ensure successful spawning and high levels of recruitment. Young et al. (1990) conducted a two-year study of six sites in Bass Strait. Settlement rate (spat collectors) was correlated with an index of parental stock abundance (CPUE). Evidence synthesised by Young (1994) indicates that, before the fisheries started, at least some populations were composed of several consecutive cohorts. Recruitment occurred all years to the eastern Banks Strait region during 1979–1983, although not always in the same beds. By contrast, no significant recruitment was observed between 1985 and 1989.

iv) Marelli et al. (1999) monitored density and recruitment of a collapsed bay scallop stock from Florida; lack of recovery was attributed to a combination of natural and anthropogenic causes, and depensatory dynamics. They suggested that recovery could take at least a decade.

v) Summerson and Peterson (1990) presented compelling evidence supporting the hypothesis that recruitment of bay scallops failed in 1987–1988 in Bogue and Back Sounds (North Carolina) due to the first recorded red tide of *Ptychodiscus* (= *Karenia*) *brevis*. Recruitment failed again during the next four years. Peterson and Summerson (1992) observed a positive relation between settlement rate (measured with spat collectors), recruitment and adult abundance across 9 beds, and showed that reduction in recruitment (relative to pre-disturbance levels) conformed to the documented pattern of immediate direct effects after the red tide. In subsequent years (1992–1994), Peterson et al. (1996) transplanted spawners from a donor site where scallops were abundant to four receiver sites where populations had not recovered. Adult density in western Bogue Sound (receiver sites) increased by 258% following spawner transplantation as compared to a non-significant change of 8% in control sounds (Back and Core Sounds), although settlement indices (spat collectors) could not confirm that the transplants succeeded through the enhancement of larval abundance.

(3) Stock-recruitment relationship in the absence of exceptional changes of spawning biomass:

i) McGarvey et al. (1993) analysed the stock-recruitment relationship in a self-sustaining stock, *Placopecten magellanicus* from Georges Bank (Sections 14.3.2.1 and 14.3.2.3). Their study was based on 11 years of survey data, including information on age structure. Time series of recruitment and annual egg production (based on age-specific fecundities) were correlated in two areas, which may imply that they constitute a self-sustaining stock (see also Section 14.3.2.1).

ii) Fífás et al. (1990) analysed recruitment of the *Pecten maximus* stock from the Bay of St. Brieuc (also believed to be self-sustaining) using a multiplicative model incorporating spawning biomass, thermal anomalies during critical periods of the reproductive cycle, and incidental mortality of pre-recruits due to fishing. The assumption

of a linear relation between spawning biomass and recruitment could not be rejected in favour of models incorporating compensatory density-dependence.

This collection of cases appears to reveal some characteristics of scallop population dynamics:

i) Recruitment is positively correlated with stock size, even at moderate to high levels of abundance. “Under-saturation” of beds may point to the existence of many unsaturated sites, even at high levels of aggregated abundance.

ii) Steady or irregularly fluctuating iteroparous stocks tend to shift to a spasmodic pattern after their abundance has been reduced (the *Pecten fumatus* and tehuelche scallop cases); alternatively, spasmodic stocks have become steady following enhancement of the spawning biomass (the Mutsu Bay case). This indicates that at low density levels strong recruitment is exceptional, probably resulting from fortuitous combinations of circumstances (e.g., right thermal triggering of spawning in a small source or reproductive hotspot).

iii) In the absence of such fortuitous combinations of circumstances, recovery of depleted beds can be lengthy and erratic (e.g., *Pecten fumatus* and bay scallop stocks); depletion events (natural or due to overfishing) tend to have long-lasting effects.

Overall, these observations are consistent with the “recruitment-limitation hypothesis” (Peterson and Summerson 1992), which may hold even at moderate to high levels of abundance. Existence of under-saturated sites, even at high levels of aggregated abundance, is expected to occur due to the contagious spatial distribution of scallop populations. Caputi et al. (1998), for example, showed that, following a spasmodic recruitment pulse in the *Amusium balloti* stock from Shark Bay (Western Australia), the area of the bottom covered by scallops was less than 10%, even at peak observed density (7 scallops m⁻²). Compensatory density-dependence (“inhibition”) has been shown to occur in very dense patches of scallops and other benthic bivalves (Section 14.3.4.3), e.g., in the tehuelche scallop stock of San José Gulf (Argentina). But even in the latter case Orensanz (1986) reported that the 1975 year-class was relatively strong in the entire region, both in lightly populated beds and in others in which compensation was concurrently demonstrated by small-scale observation of crowded patches. Ciocco and Aloia (1991) made comparable observations on other year classes.

14.3.2 Macroscale

14.3.2.1 Patterns of connectivity: metapopulation structure

Although the term “metapopulation” became fashionable only in recent years, the conceptual model associated with it has long been implicit in scallop population dynamics. Fairbridge (1953) clearly conceptualised the scallop metapopulation from the D’Entrecasteaux Channel, Tasmania (itemisation is ours):

- i) "Larvae originating from any one area in the Channel [are] distributed throughout most, if not all, of the scallop-carrying parts of the Channel.
- ii) Although the adult swims, it does not move in numbers from one area to another.
- iii) There are, therefore, more or less clearly delimited subpopulations in the various bays and straits of the Channel which must be treated, for certain purposes, as entities.
- iv) Scallops in the Channel are [most probably] a genetically homogeneous [meta]population."

Metapopulations vary in the pattern and degree of connectivity among their component subpopulations (Fig. 14.1); some examples follow:

1) Subpopulations that share a common larval pool. Fairbridge's model is one of high connectivity. The tehuelche scallop metapopulation from San Jose Gulf (Patagonia) is similarly structured (Orensanz 1986); high density beds are spread over a sparsely populated background, interconnected by larval dispersal. Thouzeau and Lehay (1988) investigated connectivity in the metapopulation of *Pecten maximus* from the Bay of Saint-Brieuc (Brittany) using a numerical simulation. Their results are consistent with the observed distribution of the reproductive stock and of areas with strong settlement, supporting the idea of intense larval flow between subpopulations. These three examples of high connectivity correspond to metapopulations confined to semi-enclosed bays with significant tidal circulation.

(2) Self-sustaining subpopulations. Sinclair et al. (1985; see also Sinclair 1987), probably looking at a larger geographical scale, suggested that many discrete aggregations of scallops are self-sustaining. This viewpoint stresses the importance of mechanisms of larval retention in the vicinity of the parental stock. They found support for this view in the correlation between observed patterns of distribution and some oceanographic features ("inductive approach" *sensu* Sinclair et al. 1985, p. 5), including shelf fronts and gyres. Tremblay et al. (1994) investigated larval dispersion on Georges Bank using a circulation model. In the simulations, the dispersing particles mimicked the behaviour of sea scallop larvae. Results indicate significant larval exchange among the three major aggregations, with self-seeding possible for two of them, but unlikely for the third. Retention of particles on Georges Bank as a whole was 10–73% before mortality; the authors concluded that Georges Bank should be considered self-sustaining. Young (1994) suggested that subpopulations in the *Pecten fumatus* metapopulation from Bass Strait (Australia) are self-sustained. Arnold et al. (1998) compared abundance and settlement indices (spat collectors) among four geographically separated bay scallop populations along the west coast of Florida. Observed lack of coherence was thought to indicate that the populations are self-sustaining, even if occasional larval exchanges between populations are sufficient to maintain genetic homogeneity (Section 14.3.2.2).

(3) Asymmetric source-sink links. Connectivity between two subpopulations is always asymmetric. Exchange of larvae between beds in the Georges Bank model, discussed above, provides an example. Extreme asymmetry is found in the case of "absolute sinks"

Closed Populations

Single Source

Multiple Sources

Figure 14.1. Schematic examples of metapopulation structure (connectivity between subpopulations). *Top*: closed, self-sustaining populations, is a good model for bay scallops from bays and estuaries along the east coast of the US and the west coast of Florida. *Middle*: single source and multiple sinks, is best exemplified by the Peruvian Bay scallop. *Bottom*: multiple sources contributing to a common larval pool, is a reasonable model for metapopulations confined to semi-closed bodies of water (e.g., the tehuelche scallop stock from San José Gulf, Argentina). See Section 14.3.2 for further information on these and other scallop cases.

(pseudopopulations). Dredge (1988) hypothesised that a spawning ground of *Amusium balloti* in Queensland is the source for a sink population located to the southwest (Hervey Bay). The most dramatic example is the metapopulation of the Peruvian bay scallop from north Chile and Peru, which extends over thousands of kilometres of coastline (Wolff and Mendo 2000), a range over which no genetic variation has been detected (Galleguillos and Troncoso 1991). The Independence Bay (Peru) subpopulation, near the center of the latitudinal range of distribution, appears to be the main source of larvae to the whole metapopulation. Some formerly extinct beds were recolonised following the 1983 El Niño event.

Most metapopulations (as exemplified by the Georges Bank's) are a mix of these basic patterns. Although life-history traits relevant to connectivity may be species- or population-specific, patterns of connectivity are always contingent upon the local oceanography. In the case of *Aequipecten opercularis* from Europe, for example, the Gulf Stream drift facilitates high connectivity along the west coast of Scotland, while the stock of the Bay of St. Brieuc (Brittany) appears to be relatively isolated, "locked" by an oceanographic eddy.

Patterns of connectivity have important implications for management. In general, the lower the connectivity, the more conservative the management should be in order to avoid the serial overfishing of the population units. Small, isolated beds are particularly vulnerable; this is the case of the small, discrete populations of *Pecten maximus* confined to bays along the west coast of Ireland (Ansell et al. 1991). Fevolden (1989) recommended that a conservative approach to the management of the Iceland scallop should treat each of the main areas (Jan Mayen, Spitsbergen, Bear Island and northern Norway) as a separate stock unit (Parsons et al. 1991). A different management issue addressed by Lewis and Thorpe (1994) is the possible effect of stock enhancement through extensive transplantation, which could reduce the fitness of receptor local populations. Some understanding of broad patterns of connectivity is also important in the design of reproductive refuges, which ideally should be located "upstream" and be self-sustaining to some extent (Section 14.6.3.2).

14.3.2.2 Metapopulation structure and geographic genetic differentiation

Low connectivity does not necessarily result in detectable geographic genetic differentiation. Since small levels of gene flow may be sufficient to erase differences, subpopulations that are isolated from a population dynamics viewpoint may not be isolated in the sense of population genetics. In the case of *Placopecten magellanicus*, for example, there appears to be enough gene flow to erase differentiation in the geographically fragmented metapopulation (Herbinger et al. 1998; Zouros and Gartner-Kepkay in Beaumont and Zouros 1989; Naidu 1991), yet there is compelling evidence indicating that subpopulations are self-sustaining (Sinclair 1987; Tremblay et al. 1994; Manuel et al. 1996, discussed below). Krause et al. (1994) estimated gene flow between three populations of the calico scallop (Marquesas Keys and Cape Canaveral, Florida, and Cape Lookout, North Carolina) based on electrophoretic study of seven polymorphic loci. They concluded that gene flow between populations was significant enough to erase any

detectable differences, yet the populations are distant enough from each other (*ca.* six degrees of latitude) to suspect that their dynamics are uncoupled (see also Arnold et al. 1998). Furthermore, results on restriction site variation of mitochondrial DNA in populations from the Atlantic and Gulf coasts of Florida were consistent with the null hypothesis of a common genetic pool (Blake and Graves 1995). The same study could not detect differences between four bay scallops populations spread over a wide geographic range (Gulf of Mexico to New England). In the latter two cases there is little doubt that the populations sampled are dynamically independent from each other.

While low connectivity does not imply limited gene flow, the opposite is true: geographic genetic differentiation is strong evidence of low connectivity. Studies of genetic variation of *Pecten maximus* around the British Islands using mtDNA and RAPD banding patterns indicate that, while there is little geographic variation overall, a stock from a semi-enclosed sea lough from Ireland (Mulroy Bay) differed significantly from populations in open water (Heipel et al. 1998, 1999); this result is consistent with other pieces of evidence indicating that populations in semi-enclosed coastal systems tend to be self-sustaining (Sections 14.3.2.1 and 14.3.2.3). Geographic genetic differentiation was early documented among scallops for *Aequipecten opercularis* (Beaumont 1991); Lewis and Thorpe (1994) found highly significant inter-site genetic heterogeneity in a study of twelve populations of *A. opercularis* around the British Islands. They suggested that, in spite of having pelagic larvae, local populations appear to be self-sustaining. On the other hand, Macleod et al. (1985) identified one allele that was consistently unique to a single year class in all populations of *A. opercularis* around the Isle of Man. They interpreted this result as indicating that larvae settling in the area (at least that year) were not the offspring of the local adult populations, and speculated that the populations were maintained largely or entirely by immigration of larvae from elsewhere. Brand et al. (1991) interpreted this as indication of a source-sink system in the North Irish Sea, and hypothesised that this was the reason for recruitment being strongest in the most heavily fished beds around the Isle of Man.

Evidence of differentiation may be found also in the comparative study of life history, including transplant experiments. Ansell et al. (1991) concluded that differences in the reproductive ecology of different populations of *Pecten maximus* indicate relative genetic isolation among stocks (a hypothesis substantiated by Mackie and Ansell (1993), and Cochard and Devauchelle (1993)), although this is not supported by allozyme polymorphisms (Beaumont et al. 1993; Wilding et al. 1998).

Manuel et al. (1996) kept larvae of *Placopecten magellanicus* spawn by parents from different areas (Georges Bank, Passamaquoddy Bay and Mahone Bay) in a large experimental mesocosm. The larvae from the different stocks had different vertical distributions, identifiable by means of a microsatellite probe (see also Section 14.3.2.3). The source populations experienced contrasting hydrographic regimes, suggesting that genetically fixed behavioural differences might have resulted from natural selection for increased retention near the parental location (Section 14.3.2.3). These results are consistent with the very low density of larvae observed by Tremblay and Sinclair (1992) in the waters between Georges Bank and the Scotian Shelf.

Other transplant experiments have shown that differences in life-history parameters have no genetic basis. For example, cross-transplants of *Aequipecten tehuelchus* in San José Gulf indicate that differences in growth rate among subpopulations are ecophenotypic (Ciocco 1992). *Placopecten magellanicus* transferred from locations where spawning is annual to others where spawning is biennial, shift to the pattern of the receiving location (Dadswell and Parsons 1994). Physiologically different shallow and deep-water populations of *Placopecten magellanicus* from Newfoundland did not differ genetically based on cDNA and microsatellite markers (Herbinger et al. 1998).

The subject of genetic diversification is treated in detail in Chapter 10 of this book.

14.3.2.3 Larval retention/dispersal: mechanisms and oceanographic scenarios

Larval dispersal has been often inferred from information on the duration of the larval stage (6–70 days in different scallop species; Orensanz et al. 1991) and vectors of residual circulation estimated from drift card data or circulation models (e.g., Roberts 1997; Thouzeau 1991b; Craig and McLoughlin 1994). Larvae, however, are not drift-cards or passive particles; larval dispersal is influenced by factors other than water circulation: diffusion, survival, and active behaviour in the water column (Cowen et al. 2000). As pointed by Craig and McLoughlin (1994), Tremblay et al. (1994) and others, the appropriate use of simulation models is to assess the sensitivity of scallop larval drift to various factors. Even subtle responses to environmental cues can have a strong influence on larval retention/dispersal. Manuel and O'Dor (1997) and Manuel et al. (1997), for example, synthesised information on vertical migration of *Placopecten magellanicus* veligers from mesocosm experiments and field studies. Following evidence suggesting that they migrate in response to both tidal and diurnal stimuli, they proposed a tidal/diel conceptual model, and applied it to the Passamaquoddy Bay and Georges Bank populations (eastern Canada). Both respond to the daily light cycle (a phenomenon observed also in other species, e.g., in *Patinopecten yessoensis*; Ito (1964); Maru et al. (1973)), but differ in their response to tidal cues. Georges Bank veligers appear to utilise baroclinic differences in tidal transport to maintain themselves on the bank. Passamaquoddy Bay veligers respond by swimming up at slack water (high and low tides) and down when currents are strongest. Such behaviour would minimise dispersal on the strong tidal currents in the Bay of Fundy. Horizontal transport resulting from vertical migration was considered by the authors as the most likely selective pressure to create and maintain these different behaviours against the homogenising effects of larval dispersal.

Coincidentally, several modelling and empirical studies (Craig and McLoughlin 1994; Swearer et al. 1999; Jones et al. 1999; Cowen et al. 2000) have emphasised the importance of larval retention near the parental ground and “self-recruitment” in populations with pelagic larvae. Ultimately, as pointed by Cowen et al. (2000), the relative significance of dispersal and retention is largely one of scale. Good settlement in the vicinity of Maria Island, Great Oyster Bay (Tasmania), in December 1987, appears, based on modelling results, to have been spawned about 15 km away from the collectors (Craig and McLoughlin 1994). This could be claimed to support larval dispersal or retention, depending on the scale of specific interest.

Association between scallop concentrations and oceanographic features is generally believed to reflect, at least to some extent, retention mechanisms. Such features include:

(1) Shelf fronts. Sinclair et al. (1985) pointed to the fact that many scallop aggregations occur in zones of transition between tidally mixed (inshore) and stratified (offshore) waters. In some documented cases recruitment appears to be associated with the seasonal development of an upper layer of warm water, as indicated by Tremblay and Sinclair (1991):

i) All areas of high concentration of *Zygochlamys patagonica* from the Argentine Shelf are associated with different types of frontal systems (Ciocco et al., Chapter 26). One of those aggregations matches a surface warm water pool (delimited by the 18°C surface isotherm), 20–30 m deep that starts to develop in spring and matures during the summer (Orensanz et al. 1991).

ii) Robinson et al. (1999) conducted a 10-year study in Passamaquoddy Bay (*Placopecten magellanicus*), in which spat collectors were deployed annually on a grid and environmental data were recorded concurrently. High-density of settlers corresponded to warmer, stratified waters that generally had higher concentration of chlorophyll-*a*.

Gallager et al. (1996) and Pearce et al. (1996) studied the ontogeny of behaviour and the settlement of *Placopecten magellanicus* larvae kept in experimental mesocosms. Consistent with the field observations mentioned above, they found that in stratified water larvae are confined to the upper layer, above the thermocline. According to these results, settlement should increase in areas where, and/or at times when, water stratification is disrupted.

(2) Frontal systems along the edge of gyres. Premetz and Snow (1953) attributed concentration of *Placopecten magellanicus* on Georges Bank to a large circular gyre that forms during the summer months, when larvae are in the plankton. The clockwise circulation gyre over the bank narrows into an intense current jet along the bank's northern edge. The shallow central part of the bank remains vertically well mixed all year, primarily due to strong tidal currents. A frontal zone separates the mixed area from the surrounding stratified waters (Tremblay and Sinclair 1991, 1992).

(3) Retention/trapping by gyres and eddies. Dickie (1955) emphasised retention in the Digby area (Bay of Fundy) in warm years, and Caddy (1979a) suggested that a counterclockwise gyre in the center of the Bay of Fundy might retain scallop larvae and influence recruitment to grounds in its vicinity (Tremblay and Sinclair 1988). Yamamoto (1964) observed enhanced settlement of *Patinopecten yessoensis* in Mutsu Bay in areas underneath eddies and slow-running water. Both are characterised by “swirling currents” that concentrate large quantities of planktonic organisms and suspended silt. “Marine snow” forms underneath during the spring, and heavy settlement of scallops and other organisms was observed when oxygen was not depleted during the summer. Heald and

Caputi (1981) found that juveniles of *Amusium balloti* settle regularly in some areas of Shark Bay (Western Australia), presumably reflecting the existence of persistent eddy systems. Thouzeau and Lehay (1989) found indication that larvae of *Pecten maximus* are retained in areas of the Bay of St. Brieuc in which gyre-clockwise residual currents were measured. Aggregation underneath gyres does not necessarily imply retention of larvae generated *in situ*. Larvae trapped into gyres could come from other areas, being concentrated (rather than retained) by the gyre. Dredge (1988) suggested that a gyre in Hervey Bay (Queensland) might act as a trap for larvae of *Amusium balloti* spawned in grounds located to the northwest.

(4) Semi-enclosed bays. Larval retention in semi-enclosed bays was stressed by Boucher (1985) for St. Brieuc Bay (*Pecten maximus*) and by Fairbridge (1953) for the D'Entrecasteaux Channel (*Pecten fumata*). Semi-enclosed, non-estuarine bays are often areas of good settlement. This is the case of Mutsu Bay in Japan (Yamamoto 1964), San José Gulf in Patagonia (Orensanz 1986), Bogue Sound in North Carolina (Gutsell 1931), and the Bays of Brest and Saint-Brieuc in Brittany (Boucher 1985). Stocks within these bays are, in general, metapopulations with strong connectivity that may play an important role supplying larvae to adjacent open grounds.

(5) Coastal topography. Good settlement has often been observed in association with headlands and prominent features of the seabed, possibly as a result of interaction between coastal topography and wind- or tidally-induced circulation. Good recruitment of *Aequipecten tehuelchus* off the south coast of San Jose Gulf (Patagonia) almost always occurs at leeward of prominent coastal features, perhaps due to eddies generated by strong SW winds (Orensanz 1986). Particular areas adjacent to coastal headlands or prominent bottom features consistently attract settlement of *Pecten fumatus* in Bass Strait (Young 1994, p. 337) and *Amusium balloti* in Queensland (Gwyther et al. 1991). *Patinopecten yessoensis* in the Okhotsk Sea settles preferentially at the foot of newly-built pier walls or beneath kelp beds (Kalashnikov 1991, p. 1059).

(6) Estuarine-like circulation, which provides a mechanism of larval retention well documented for many invertebrates, has been invoked for scallops by Moore and Marshall (1967) and Naidu and Anderson (1984).

Although relationships between stock location and oceanographic features are frequently invoked, they have been rarely substantiated by process-oriented studies (the “deductive approach” *sensu* Sinclair et al. 1985: p. 5).

14.3.2.4 Metapopulation models

Metapopulation models have been discussed by Hanski (1998). Botsford (1995) and Botsford and Hobbs (1995) described the population dynamic theory appropriate to harvested metapopulations of marine invertebrates, in which subpopulations are linked by meroplanktonic larvae. Their modelling approach, which explicitly considers the spatial

structure of these stocks, was discussed using crustacean fisheries and the tehuelche scallop stock of San José Gulf (Argentina) as examples. This is a promising direction for the modelling of scallop metapopulation dynamics; models of larval dispersion (Section 14.3.2.3) are a first step.

14.3.3 Mesoscale

14.3.3.1 Persistence, extinction and resurgence of subpopulations

In the preceding section we addressed the general arrangement and connectivity of subpopulations in a metapopulation. Here we focus on the individual subpopulations. The latter tend to be more or less discrete units (“beds”) in the case of bivalves (e.g., Lasta and Bremec 1999). Sinclair et al. (1985) emphasised the unappreciated significance of the well-known fact that many commercial scallop fishing beds are recurrent in location and spatially discontinuous. In the northwestern Atlantic some have been observed and exploited in precisely the same locations for more than a century. They speculated that this supports a connection between scallop fishing beds and oceanographic features (shelf fronts, gyres, et al.) facilitating larval retention.

Bed discreteness is well known to fishers, who identify them by name in virtually every scallop fishery. They are recognised *de facto* when sampling surveys are designed, or when the origin of the catch is recorded. Yet, the dynamics of beds has received little attention from scientists. Information of the type “*Bed A has not been fished since xxx*”, “*We found a new bed off xxx*” or “*Bed B used to have three times its present extension*” is rarely treated formally in the technical or scientific literature. Over recent years, however, the origination, extinction, persistence, expansion, contraction and shape of beds have started to attract due attention, facilitated by the expanding capabilities to analyse geo-referenced data such as GIS and spatial statistics (see Section 14.4.3). The significance of this subject for the analysis of the fishing process and for the implementation of spatially-explicit harvesting strategies should be obvious.

14.3.3.2 Relation between abundance and area occupied by a subpopulation

As the size of a subpopulation (N) changes over time, the area that it occupies (i.e., the extension of the bed, A) and the overall density (N/A) are also likely to change. Analysing this process, the most basic in bed dynamics, requires the development of formal methods to draw the boundary and estimate the extension of the bed (Section 14.5.2). A power function relation between area occupied (A) and abundance (N), i.e., $A \propto N^\beta$, where β is a constant, is more or less implicit in several models, for example in the “proportional density” and “constant density” models (β respectively equals 0.5 and 1) discussed by Hilborn and Walters (1992).

Caddy (1989b) introduced a graphical model of the spatial expansions and contractions of a sedentary population with pelagic larvae (Fig. 14.2). Habitats within the maximal range of distribution rank from “favourable” to “unfavourable”. When total population abundance increases, the range of distribution expands into unfavourable

habitats, and when abundance declines the range contracts to the most favourable habitats. Suitability of a site, defined in terms of persistence of occupation through time, has two components:

- i) Larval availability, determined, for example, by the existence of oceanographic systems that facilitate the retention of larvae.
- ii) Availability of suitable benthic habitat, determined by factors affecting post-larval growth and survival, e.g., adequate substrate, good food supply, low density of predators, etc. (Thouzeau 1991b).

In Caddy's (1989b) and other idealised models of geographic range dynamics (e.g., McCall 1990) suitability gradually vanishes away from a central core; range contraction is visualised as a gradual retraction of the periphery. In more realistic scenarios, patterns associated with stock contractions more likely involve the "vacuolation" of dense cores, fragmentation of beds, and extinction of some beds.

Another popular model of CE dynamics was McCall's (1990) extension of the Ideal Free Distribution (Fretwell and Lucas 1970). He developed the model with pelagic fishes in mind, but presented an extension for the case of benthic shellfish. The assumptions of the latter are not reasonable for the case of scallop stocks.

The relationships between the area occupied by a subpopulation, its size, and catchability have been investigated for several finfish stocks during recent years (Crecco and Overholtz 1990; Rose and Leggett 1991; Swain and Wade 1993; Marshall and Frank 1994; Swain and Morin 1996; Rose and Kulka 1997). The spatial dynamics of finfish populations differs from that of sedentary organisms in that changes in the area occupied are often a short-term result of individual movements in the first, but are mediated by intergenerational processes (renewal) in the second (at least in the absence of fishing or catastrophic mortality). Yet, conceptual and formal models introduced recently for finfish stocks are applicable to scallop bed dynamics.

14.3.4 Microscale

In this section, we consider the small-scale spatial structure of scallop populations, and its implications for density-dependent processes. We do not discuss the factors and processes that underlay those patterns (microhabitat selection, movements, etc.), which were reviewed in the first edition of the book by Brand (1991, pp. 550–564) and Orensanz et al. (1991, pp. 662–667). See also Chapter 12 (Brand).

14.3.4.1 *Density, neighbourhoods and concentration*

Among benthic ecologists there is perhaps no notion better established than "*density*", the number of individuals found per unit of area. Its analysis is central to the assessment of stocks of benthic sedentary organisms. In a typical study, "quadrats" are sampled according to some pre-established design (typically at random locations, eventually stratified), density is estimated, and departure from spatial randomness is investigated

Figure 14.2. Caddy's graphical model of the geographical contraction/expansion of a subpopulation. Habitats within the maximal range of distribution rank from "favourable" to "unfavourable". When total population abundance increases, the range of distribution expands into unfavourable habitats, and when abundance declines the range contracts to the most favourable habitats. (Modified from Caddy 1989b).

using the frequency distribution of quadrat counts (e.g., Elliott 1977; Section 14.5.3). Yet, Orensanz et al. (1998) argued that emphasis on the observation of density at arbitrary locations, together with reliance on quadrats for its measurement, have obscured the significance of a related but distinct concept: *concentration* or *crowding*. The latter is density experienced by an individual within a certain *neighbourhood* (as opposed to density measured by an observer at arbitrary locations). If the location of the individuals in a given region is conceived as a spatial process, then density and concentration capture the first and second order properties of that process (analogous to familiar notions of mean and variance).

The analysis of concentration requires meaningful conceptual constructs, and formal models to render these notions tractable:

(1) The notion of “neighbourhood” provides a conceptual framework. Defined with respect to an individual, it is a spatial region within which a certain interaction between the individual and its environment (including other individuals of its own kind) is effective (or, from the viewpoint of the observer, within which its effectiveness is evaluated) (Orensanz 1986). Various neighbourhoods can be defined, each relative to a specific process:

- i) *Trophic*, relative to resource utilisation, eventually leading to competitive interactions.
- ii) *Reproductive*, related, in the case of broadcast spawners, to gamete dilution away from the individual.
- iii) *Sensory*, relative to perception of environmental conditions, including the presence of conspecific, predators, etc.

(2) The theory of stochastic spatial point processes provides an appropriate formal framework (Ripley 1977, 1981; Diggle 1983; Cressie 1991). Observed patterns of distribution of individual animals in space are modelled as realisations of spatial point processes; in the simplest case neighbourhoods are modelled as circular isotropic regions centred on the individuals. Most individuals in populations with an aggregated spatial distribution experience a high concentration, even if high-density patches are scarce and small (Orensanz 1986). This has important and self-evident implications in the case of density-dependent processes (resource depletion, fertilisation rate in broadcast spawners, predator-prey interactions, spatial allocation of fishing effort, etc.), that may affect a large fraction of the population even if they operate only over comparatively small areas (Orensanz et al. 1998).

“Neighbourhoods” are defined by interactions, not by an absolute metric ruler. For example, trophic neighbourhoods of suspension feeders may be extensive, particularly in the presence of turbulence or flow in the benthic boundary layer. The neighbours of a spawning individual, on the other hand, are the conspecific located in close proximity, at a distance such that gametes can cross-fertilise.

14.3.4.2 Concentration profiles

While ecologists have focused mostly on mean concentration or crowding for assessing spatial pattern (e.g., Elliott 1977), interest in the *distribution* of concentration in a population arose in the 1980’s among natural resource scientists. First, Clark (1982, 1985) introduced such distributions (as *concentration profiles*) as a way of describing the amount of resource found at different densities, and to investigate the response of harvesters to such patterns. The observational scale of interest for the analysis of these profiles is necessarily large, commensurate with the spatial scale of the fishing process

(i.e., the observational scale upon which harvesters make tactic decisions). Profiling of concentration at smaller scales was first proposed by Orensanz (1986, as distributions of “*neighbourhood density*”, his fig. 3:e). Concentration profiles are commonly classified into “types” (Clark 1982, 1985; Hilborn and Walters 1992, pp.184–188; Orensanz et al. 1998, their fig. 8) generally associated with density frequency distributions at the same scale of observation (Fig. 14.3); the definition of types is not consistent in the literature.

In traditional fishery science there is an emphasis in abundance, but in the case of sedentary resources the concentration profile for a given abundance level is an important consideration as well. For example, the rates of fishing mortality and of fertilisation are both concentration-dependent (Sections 14.3.4.3 and 14.4.3): divers only harvest scallops in dense patches, and the chances of fertilisation are higher for crowded scallops. In other words, it is not the same thing to have 100 scallops spread over one km², or to have them crowded in 10 m²: In the first case they will be unattractive to divers, and unlikely to get their eggs fertilised; the opposite holds in the second case. This creates a delicate situation in which divers target those individuals that are most likely to reproduce successfully. This phenomenon (first addressed by Gross and Smyth 1946) is one of the most likely causes of recruitment overfishing in benthic fisheries. The problem is well illustrated by the dramatic contrast between the concentration profiles of the tehuelche scallop stock of the San José Gulf before and after the fishery collapsed (Fig. 14.4). A survey of the entire metapopulation was conducted in 1975 (Orensanz 1986; Prince and Hilborn 1998, their fig. 2) and again 20 years later (Ciocco et al. 1997) after the fishery had collapsed, presumably due to overfishing. While a large fraction of the scallops lived at high concentrations in 1975, the scallops left after the collapse were not only few but also highly diluted (Orensanz et al. 1997). The vertical lines in the figure show the density threshold for commercial diving harvesting in 1975 (*ca.* 25 scallops m⁻²). Between then and 1996, mostly due to a series of economic crises and a devalued peso (scallops are an export product) the density threshold dropped to very low levels.

14.3.4.3 Density- vs. concentration-dependence; compensation vs. depensation

Density-dependence in scallop metapopulations is likely to be significant only during benthic stages (larval settlement through fertilisation). Most density-dependent interactions have small operational scales, as individuals are influenced only by their neighbours (Orensanz et al. 1998). Density-dependence can be compensatory or depensatory. In the first the *per capita* reproductive contribution decreases at higher densities, a result of increased competition for resources, slower growth, less energy available for reproduction and increased mortality. In depensatory density-dependence (also known as inverse density-dependence or “Allee effects”) the reproductive contribution *per capita* decreases as density decreases. This is the case of fertilisation rate in broadcast spawners: the less neighbours around, the lower the chances of fertilisation.

The effects of localised (small-scale) density-dependence on the (large-scale) dynamics of the metapopulation are mediated by larval dispersal. Thus, it is convenient to distinguish between pre- and post-dispersal density-dependent mechanisms (Botsford and Hobbs 1995), whether these are compensatory or depensatory. Pre-dispersal density-

Figure 14.3. Five general types of concentration profile. *First column:* concentration profiles. *Second column:* corresponding distributions of density (concentration - the y-axis in figures of the first column - is the product of the two axes of the figures of the second column). (Modified from Orensanz et al. 1998).

Figure 14.4. Concentration profiles for two surveys of the tehuelche scallop stock from San José Gulf conducted in 1975 and 20 years later, after the fishery had collapsed. Notice that the scallops left are highly diluted. The vertical lines show the density threshold for commercial diving harvesting in 1975. Between then and 1996 the density threshold dropped to very low levels, mostly due to a series of economic crises and a devalued peso (scallops are an export product). (Modified from Orensanz et al. 1997).

dependent processes are those that affect the reproductive output either directly (e.g., fertilisation success), or indirectly (e.g., density-dependent growth). They depend on the concentration profile of the populations, which summarise the density conditions experienced by individuals (concentration). Post-dispersal processes affect the rate of recruitment through the effect of resident densities on larval settlement and survival of pre-recruits. Figure 14.5 summarises the types of density-dependence most frequently considered for benthic sedentary invertebrates with broadcast spawning, external fertilisation, and pelagic larvae, such as scallops. Notice that in the lower-left panel of Figure 14.5 the solid line represents an “envelope” or “boundary” indicating the *maximum* density of new settlers expected for a given density. In all the other panels the solid line corresponds to the expected level (*mean*) of the response variable (gametes produced per local resident, fertilisation rate, density of new settlers) conditioned on the density of resident adults.

Figure 14.5. Types of density-dependence most frequently presumed and/or investigated for benthic sedentary invertebrates, which, like scallops, have broadcast spawning, external fertilisation, and pelagic larvae. Notice that in the lower-left panel the solid line represents an “envelope”, indicating the *maximum* density of new settlers expected for a given density of residents. In all the other panels the solid line corresponds to the expected value (*mean*) of the response variable, conditioned on the density of resident adults. K: local carrying capacity; T1-T5: density threshold levels; LA is an index of larval availability.

(1) **Pre-dispersal depensation: fertilisation rate.** Pennington (1985) demonstrated that per-capita fertilisation rate (the fraction of the eggs produced by each individual that get fertilised) increases with density in sea urchins (as scallops, external fertilisers). This effect was already foreseen by Belding (1910: p. 26): “there are a great many chances in nature against fertilisation of the egg. Scallops may be some distance apart and the spermatozoa must travel far before they can meet the egg [, and] the male cell can only be attracted to the egg from a short distance”. Gross and Smyth (1946) first suggested that the elimination of the densest segments of a bivalve metapopulation may have a disproportionate effect on reproductive success and renewal (Fairbridge 1953: p. 38; Orensanz 1986), and that this should be a major concern in bivalve fisheries (Levitan and Sewell 1998).

(2) **Post dispersal depensation: attraction of settling larvae to conspecifics.** Evidence for scallops (unlike other epibenthic bivalves, like oysters) is very limited. Vahl (1982) suggested that recruitment success of the Icelandic scallop is dependent on the density of resident adults.

(3) **Pre-dispersal compensation: competition.** Competition for limited resources has a hierarchical sequel of compensatory effects:

i) **Depletion of food resources.** Density-dependent depression of growth and survival rates are commonly assumed to be linked to *depletion of food resources* and intraspecific competition for food (Frechette and Bourger 1985; Orensanz 1986). This implies that the resource in question is in short supply, or that feeding individuals can deplete the resource in their neighbourhood. Seston depletion by suspension feeding bivalves has been invoked or demonstrated at different scales, ranging from the neighbourhood of individuals kept in still water to large water bodies. Dense scallop populations have the capacity to deplete phytoplanktonic resources in confined coastal water bodies (Mori 1975; Vahl 1979; Orensanz 1986; Bricelj et al. 1987).

ii) **Individual growth.** Depressed individual growth at high experimental density was shown by Belding (1910) for *Argopecten irradians*. Similar results have been obtained in other studies (Orensanz et al. 1991). Inferential evidence of density-dependent growth in natural field populations usually consists of negative correlation between density (or biomass) and size-at-age (Cooper and Marshall 1963; Gruffydd 1974; Orensanz 1986). Orensanz (1986) found significant differences in growth among four year-classes of *Aequipecten tehuelchus* in the San Roman bed (Patagonia); growth rate was negatively correlated with density. Density-dependent depression of growth rate became evident in several indices of condition when average local biomass exceeded 1 kg m^{-2} . At larger scales, long-term trends in growth rate have also been attributed to density-dependent effects. *Patinopecten yessoensis* sown on the seabed of Mutsu Bay grew twice as fast in the sixties than in the seventies (Ventilla 1982: his fig. 29, p. 367). Most areas were overstocked in the interim period, when the bay apparently reached its carrying capacity.

iii) **Recruitment to the Fishery.** Density-dependent effects on growth can be strong enough to affect the age of entry to the fishery, to the extent that they are worth considering by managers. The best known case is that of *Patinopecten yessoensis* from Mutsu Bay (Ventilla 1982: his fig. 28). For sown scallop to reach commercial size within 2.5–3.5 years, they must be distributed at a density of $5\text{--}6 \text{ m}^{-2}$. Overstocking, resulting in slower growth, delays significantly the time at which scallops can be harvested. The Tehuelche scallop population from San Roman provides an example involving a natural stock (Orensanz 1986). The 1974 year-class that grew under low density conditions, reached commercial size (on average) at the age of 1.4 years, while the 1975 year-class, that grew under high density conditions, reached the same size at the age of 2.2 years. *Pecten fumatus* from Port Phillip Bay (Australia) attained a shell length of 70–80 mm at the age of 2.5–3.5 years during the sixties, at the onset of the fishery. Twenty years later, the same size was reached at age 1+ (i.e., more than one year sooner). This was interpreted by Gwyther and McShane (1988) as a density-dependent effect.

iv) *Mortality*. Density-dependent mortality of suspension-feeding bivalves attributable to starvation has been rarely demonstrated for natural populations. Crowding has been found to be the cause of mass mortality events under exceptionally high density conditions, like in *Patinopecten yessoensis* cultivated in Japan (Mori 1975; Ventilla 1982; Aoyama 1989). Intermediate rearing in Mutsu Bay (Japan) has been limited to 700 million spat in order to avoid the deleterious effects of density-dependence. Caddy (1989a) speculated that density-dependent predation may be effective in maintaining low-density levels in *Placopecten magellanicus*. Noel (1997) reported extremely high mortality during years of exceptional abundance in *Pecten fumatus* from Port Philip Bay (Australia), which could perhaps be attributed to compensatory density-dependence. Besides direct effects through depletion of food or oxygen, and attraction of predators, the effect of density on mortality can be indirect or lagged: (i) retardation of growth due to starvation could protract exposure to some predators, and (ii) periods of environmental stress could be more harmful to individuals previously exposed to food shortages (Orensanz et al. 1991).

v) *Production* should reflect the aggregated effects of density-dependence on growth, survival and recruitment. The San Roman (Patagonia) population of *Aequipecten tehuelchus* (Orensanz 1986) provides a well-documented example. Mean biomass at the core of the bed showed cyclical variation over a 15-year period, with maxima of 1.3 kg m⁻² reached every 5 years. This ceiling was set by compensatory mechanisms that became detectable above a mean biomass of 1.0 kg m⁻². While average biomass almost doubled from 1975 to 1976 (521 to 980 g m⁻²), annual production remained constant (762 to 767 g m⁻²), even when there was not a remarkable change in age structure. This was indicative of an effective local carrying capacity. Meat production was 382 g m⁻² yr⁻¹. Coincidentally, Charpy-Roubaud et al. (1982) estimated (independently) that phytoplankton production in the same area could support an annual production of 379 g m⁻² yr⁻¹ of herbivore bivalve meats. The bed was at its carrying capacity during 1974–1976, with scallops monopolising suspended food resources. Estimated filtration rate for the dense core bed was 14,400 L d⁻¹ of water, roughly equivalent to the overlying water column (8,000–17,000 L). In an empirical study conducted on the same bed a few years later, Ciocco (1991) estimated values remarkably similar: 359 g m⁻² yr⁻¹ and 368 g m⁻² yr⁻¹, respectively. The relationship between stocking density and production has been well established for the bottom culture of *Patinopecten yessoensis* in Mutsu Bay, Japan (Aoyama 1989). Maximum yield is 1.2 kg m⁻² (less than 6 scallops of age 3+ per m²). At a larger scale, it is thought that the bay as a whole reached its carrying capacity during the late seventies (Ventilla 1982). Mass mortality events in 1975–1977 were attributed to overstocking. It is estimated now that the bay can support a maximum of 700 million spat yr⁻¹ under intermediate culture, keeping the annual production (crop) at 50,000–60,000 tons.

vi) *Reproductive Potential*. Gonad weight is - roughly - a power function of size, and potential fecundity is proportional to gonad weight. Thus, density-dependent depression of growth rate and production can result in reduced fecundity. Orensanz (1986) found that the relative gonad weight of *Aequipecten tehuelchus* showed the effects of density-dependent growth before any other index of condition. Reproductive output during a

high-density year (1975) was 80% smaller for age class 1+, and 25% smaller for age class 2+ than during a low-density year (1974). *Patinopecten yessoensis* from Mutsu Bay showed a 20–25% reduction in ovary weight between the sixties and the seventies, when growth rate declined due to overstocking (Ventilla 1982).

(4) Post-dispersal compensation: inhibition. A negative relationship between the density of adult residents and settlement/early survival rate has been observed, among suspension-feeding bivalves, in field populations of cockles (Hancock 1976; André and Rosenberg 1991; Bachelet et al. 1992) and scallops (Vahl 1982; Orensanz 1986). The functional form of the relationship takes the form of an “envelope”: given a certain density of residents there is a *maximum* possible number of settlers, but that number can be as low as 0 if settlers are not available. It is unclear whether the main inhibitory effect involves pediveligers being inhaled by resident adults, or juveniles being out-competed by residents.

Two factors contribute to the complexity of any postulated mechanism of negative adult-larval (or juvenile) interaction. First, refuge provided by primary settlement substrates elevated from the bottom or located away from adult habitat (Minchin 1992) may alleviate negative interactions. Second, post-settlement dispersal of bivalves (Sigurdsson et al. 1976) may result in different areas for settlement and recruitment. Juvenile scallops can disperse attached to algae, seagrass, etc. (Ingersoll 1887; Orensanz 1986), drifting suspended from a byssal filament (Sigurdsson et al. 1976), or by means of their own movements. Vahl (1982) studied recruitment to a bed of *Chlamys islandica* over a 9-year period. Juveniles settled in unidentified areas outside the bed, and immigrated at the age of 2 years or older.

(5) Tradeoffs between compensation and depensation occur, for example, when the reproductive contribution of a spawner increases with density due to increased fertilisation rate (pre-dispersal compensatory density-dependence), but decreases due to reduced growth rate (pre-dispersal depensatory density-dependence). Such a balance was hypothesised for scallops by Orensanz (1986) and Kalashnikov (1991, p. 1061). Levitan (1991) investigated the same phenomenon in sea urchins, and estimated that the reproductive contribution per capita was very stable over a wide density range due to the balance between the two antagonistic processes.

14.4 THE FISHING PROCESS

The *fishing process* is the sequence of actions through which a resource is located, harvested, and depleted by a *fishing force* (“the fleet”) composed of discrete *fishing units*. The latter range from individual rakers and divers, to offshore industrial dredgers and trawlers (Section 14.4.1). The *fishing mortality* imposed on the population is related to the amount of *fishing effort* exerted by the fleet (Section 14.4.2). If fishing operations were spread at random and all scallops were identical to each other, all the scallops in the harvested population would have the same chance of being caught by a unit of effort. Under this assumption (*homogeneity*) fishing mortality would be simply proportional to

fishing effort⁶. In reality, however, beds with higher density or closer to port tend to be harvested more intensely. The analysis of fleet behaviour and the spatial allocation of fishing effort (Section 14.4.3), depletion (Section 14.4.4) and variable vulnerability (Section 14.4.5) are important to understand where fishers fish, and why they fish where they fish. This is a central issue in the assessment and management of benthic stocks. The assessment of the fishing process attends also to several aspects of gear performance: *area fished* with a unit of effort, *gear efficiency* and *gear selectivity* (Section 14.4.6).

14.4.1 Types of Fishing Gear used in Scallop Fisheries

Scallop harvesting techniques fall into four main groups (see regional chapters in this book for further information), each of them presenting particular problems for the measurement and standardisation of fishing effort (Caddy 1979b):

(1) Dredging. Dredges and dredge behaviour have been described for many fisheries, including those in Britain (Baird 1959; Mason 1970; Chapman et al. 1977; Noel 1980; Franklin et al. 1980; Howell 1983), France (Dupouy 1978; Noel 1982; Fifas 1991), Ireland (Gibson 1956), eastern Canada and New England (MacPhail 1954; Bourne 1964, 1966; Caddy 1968; Cook 1983; Robert and Lundy 1988), southeastern US (Cummins 1971), Japan (Ito 1964; Yamamoto in Imai 1971; Ventilla 1982), Australia (Fairbridge 1953; Young and Martin 1989; Cover and Sterling 1994), and Argentina (Olivier and Capitoli 1980; Orensanz et al. 1991). Scallop dredges range from rigid-framed, with or without teeth, to essentially modified beam trawls with upper and lateral rigid supports and a lower sweep chain. Cover and Sterling (1994) investigated scallop dredges from an engineering perspective in a comparative experimental study.

(2) Trawling, employed in the US calico scallop fishery (Rivers 1962), in tropical *Amusium* fisheries (Heald and Caputi 1981; del Norte et al. 1988; Young and Martin 1989; Dredge 1994), in the *Pecten ziczac* fishery of South Brazil (Pezzuto and Borzone 1997), in the Patagonian scallop fishery of the Argentine Shelf (Ciocco et al., Chapter 26), and in the *Pecten jacobaeus* fishery of the Adriatic (Hall-Spencer et al. 1999).

(3) Diving is utilised, at least to some extent, to catch almost every commercial scallop species, including those that are harvested primarily with dredges, like *Placopecten magellanicus* in Maine (Dow 1969; Tamanini 1985), or *Pecten maximus* and *Aequipecten opercularis* in Britain (Hardy 1981). Many coastal scallop fisheries are caught exclusively by divers (often because of regulations banning dredges and trawls), e.g., *Pecten vogdesi* in the Gulf of California, *Aequipecten tehuelchus* in San José Gulf (Argentina; Ciocco et al., Chapter 26), *Zygochlamys patagonica* in southern Chile, and *Argopecten purpuratus* in northern Chile and Perú (Stotz and González 1997b).

(4) Hand-operated devices, including rakes and the brideog, a long-poled hand net employed in Ireland (Gibson 1956).

Gear evolves as fisheries develop, often through technological improvements that result in punctuated increments in efficiency, as is well illustrated by commercial scallop diving. Women divers of the Russian far east (“baba seals”, Kalashnikov 1991; p. 1073), who picked *Patinopecten yessoensis* with no diving gear at all, were among the first to do it commercially. The first compressors introduced were hand-operated (Luo 1991). During the second half of the century, the “hookah” became the basic system utilised world-wide. A hookah team involves fishers with skin-diving gear getting air from on-board compressors through flexible hoses.

14.4.2 Effort and Fishing Mortality

14.4.2.1 Effort data

Effort data are most often provided by the fishers themselves (catch slips, logbooks, interviews) or the administrative track of the catch (catch/sales slips). On-board observer programs are a possibility in the case of industrial fisheries, like the Argentine offshore fishery for Patagonic scallops (Ciocco et al., Chapter 26) and the Alaska fishery for weathervane scallops (Turk 2000). Aerial surveys are an option in the case of small-scale or artisanal fisheries where the effort, spread over extensive and intricate coastal regions, is difficult to monitor with the methods listed above.

Fishing intensity (defined as the amount of effort *applied per unit of area* over a given time interval) can be assessed indirectly in the case of trawls and dredges, since the gear leaves readable marks on the substrate and on shelled organisms encountered by the gear but not caught. Depending on the nature of the substrate, dredging or trawling intensity can be mapped with the help of side-scan sonar. Encounters with the gear are often recorded in the shell of surviving scallops as *shock marks*, which provides a way to map fishing intensity with fine spatial resolution (Caddy 1972, 1989a; Naidu 1988).

14.4.2.2 Effort units

The operational time of a fishing unit can be partitioned into a number of components (Hilborn and Walters 1992): *travel time* to fishing grounds (which can take up a considerable fraction of the time budget), *search time*, *setting time* (spent in shooting and hauling the gear), *fishing/catching time* (the period during which the gear effectively operates), and *processing time* (handling of the catch on the deck). Detailed analysis of these components may prove informative. The ratio between handling and search times, for example, has been used as an index to describe stages in the development of a fishery (Caddy 1979a). Handling time should be relatively more important at early stages, whereas search time is expected to increase as the resource is depleted. In the case of dredgers and trawlers a unit of effort (e.g., a fishing day) often includes several dredge or trawl hauls. Catch and handling time per haul (which includes time spent culling and processing the catch on the deck) are positively correlated with abundance (Caddy 1975, 1979a, 1989b). Search time has decreased consistently in many scallop fisheries during recent years as a result of improved navigational and hydroacoustic equipment. Search

efficiency is also related to the power of the engines; Fifas (1991) incorporated this relationship in his analysis of catchability in the St. Brieuc Bay (France) scallop fishery.

The choice of units to express effort is more often than not determined by the nature of the data available. Sources of variation increase for aggregated effort units like fishing days or trips, vs. - for example - hours dredged. However, even coarse effort information (for example fleet size) can be useful in the absence of more refined data. Caddy (1979a) found good correlation between estimated annual fishing mortality and fleet size for the Digby fishery for the period 1941–1951 (effort data and estimates of fishing mortality rate from Dickie 1955). This permitted the estimation of fishing mortality rate using fleet size data for other years, assuming that the fishing power of the boats was constant. Estimates can be improved with additional information, as Caddy did with the duration of the fishing season, and the proportion of “fishable days” (when weather allows fishing) during the open season.

14.4.2.3 Components of fishing mortality under homogeneity assumptions

Under homogeneity assumptions, fishing mortality is decomposed into the number of effort units applied per unit of time and the *catchability*, approximately the fraction of the population removed by a unit of effort. The catchability can be calculated from the area fished by a unit of effort (e.g., the *area swept* by a dredge haul), the total area occupied by the stock, and the efficiency of the gear (the fraction of the scallops in the path of the gear that are caught). The homogeneity assumptions, however, do not hold in real scallop fisheries (Caddy 1975, 1979b, 1989a). The spatial allocation of fishing effort is random or haphazard only in controlled fishing experiments (e.g., Iribarne et al. 1991), and organisms are never randomly distributed at the operating spatial scale of the fishing process (random patterns can occur at smaller scales, see Section 14.5.3.3). Besides problems derived from nonrandom effort allocation, catchability varies in relation to an assortment of variables that can be roughly classified into:

- i) *Technological factors*. Fishing power of effort units depend on many factors such as boat design, quality of the equipment, type of gear, fisher's experience, etc. Trawling speed, for example, affects catchability in the fisheries for highly mobile *Amusium* species (Joll and Caputi 1995). Gear efficiency is discussed in Section 14.4.6.
- ii) *Environmental factors* affecting the performance of fishing units or fishing gear: bottom quality, weather conditions, water visibility, depth, etc. Catchability increases after the first passes with the Australian dredge, a result of flattening of the substrate (Young and Martin 1989; Currie and Parry 1999).
- iii) *Biological factors*, mostly related with behavioural aspects related to gear avoidance.

The effect of all these factors may vary over time, at various scales:

- i) *Within-year fluctuations* can be associated with environmental conditions affecting fishing power (e.g., seasonality of weather conditions), or with biological factors.

Fluctuations in vulnerability due to behavioural cycles range in frequency from diel to annual.

ii) *Long-term trends* often reflect the evolution of gear design (Section 14.6.1). Contractions and expansions of the geographic range of the stock (or of the area harvested) can also have a substantial effect on catchability.

14.4.2.4 Relative fishing power and standardisation of effort

Stock assessment requires aggregate estimates of fishing effort. Since the fishing force is always heterogeneous, the aggregation of effort requires some form of standardisation based on the relative fishing power (*RFP*) of the fishing units. The *RFP* of the fishing units can be assessed experimentally, or through the analysis of *CPUE* data. Experimental studies are often impractical, and have been used mostly to assess one particular component of *RFP*: gear performance (Section 14.4.6).

CPUE analysis requires stratification of the data by meaningful categories or factors, such as statistical area, time (year, season, month), time of the day (day, night), and type of fishing unit, defined according to various attributes. The latter may include fishing gear (when several fishing styles coexist in the fishery), size of the vessels (measured in tonnage or length) or power of their engines (measured in HP, often used in dredge and trawl fisheries), skill and experience (important in the case of commercial divers). The intuitively appealing model elaborated by Robson (1966) and Gavaris (1980) assumes that the effects of various sources of variation are *multiplicative*. If, for example, abundance increases from one year to the next (year factor), the *CPUE* for all vessel or gear types may reflect the change similarly and increase by a fixed proportion (as opposed to a fixed amount). This model can be fitted to stratified *CPUE* data with the help of any statistical package that handles multiple regression. Alternatively, the problem can be approached through GLIM (Generalised Linear Models). Sources of variation in *CPUE* may interact with each other. For example, the *RFP* of different boats may vary over space: some crews may have a better knowledge of certain regions, the *RFP* of small and large vessels may rank reversibly in inshore and offshore grounds, etc. Interaction terms can be added to the multiplicative model to account for these effects. One problem, however, is often insurmountable: the unbalanced distribution of the information, particularly when there are many empty cells in the data matrix (combinations of factor levels for which there is no information).

14.4.3 Spatial Patterns of Effort Allocation

The dynamic implications of the spatial structure of the population and effort allocation were first explored formally by Caddy (1975) by means of a simulation model of the Georges Bank scallop fishery. Overall, fishing mortality estimated on the basis of area swept (homogeneity assumptions) were shown to underestimate grossly the actual mortality, due to the contagious nature of fishing effort. When homogeneity assumptions do not hold, the spatial allocation of fishing effort is controlled by a hierarchy of factors:

- i) *The spatial distribution of the resource.*
- ii) *Location-specific effects*, generally related to accessibility and operational costs: distance from port, exposure to weather, depth, type of bottom, etc.
- iii) *Performance of the fishing unit at a given location*, which may or may not vary significantly and consistently among locations.

Simply stated, the first condition for fishing to occur at a location is that there is something substantial to be fished, the second that the location is accessible, and the third that the fishing gear has the appropriate power at that location.

Fishers travel from port to fishing beds, search for fishable concentrations, probe along the way, deploy the gear, fish, process the catch, re-deploy the gear, etc. Elaborate search behaviour, density thresholds at which divers move to a new location, and sequential depletion of beds are easiest to observe in diving fisheries (Orensanz 1986), but also in trawl and dredge fisheries when detailed data are available. Turk (2000) investigated the behaviour of individual vessels in the Gulf of Alaska using a GIS platform and logbook information, providing the most detailed study case available on the behaviour of a scallop fleet. As an illustration, Figures 14.6 and 14.7 show serial effort allocation to six beds near Kodiak Island, plus two periods of search. Effort shifted to a new bed after a *CPUE* threshold of *ca.* 2,000 kg km⁻² was reached.

Various sequential patterns of effort allocation have been mentioned for other scallop fisheries:

- i) Expansion of the area fished, typical of developing fisheries in which effort extends progressively to beds more distant from port, a case nicely illustrated by Brand et al. (1991) with the scallop fisheries of the North Irish Sea.
- ii) Contraction of the area fished. Boats may be scattered at the opening of the fishery, and aggregated once dense beds are located (Fairbridge 1953).
- iii) Serial depletion and shifts, described above for the Alaska fishery, have been reported in many other cases (Fairbridge 1953; Dickie 1955; Gibson 1956; Dredge 1986; Ansell et al. 1991; Briggs 1991). Renzoni (1991) described this pattern for the Italian scallop fishery: "an exploitable bank is discovered and the word spreads among the fishermen. The bank is exploited completely or until it is no longer 'economic' to exploit the area".
- iv) Spontaneous rotation was described by Blake and Moyer (1991, p. 899) for the calico scallop fishery. Beds off Cape San Blas (Northern Gulf of Mexico) are harvested only every 2–3 years, after other stocks have been depleted.

Problems of interest in the analysis of effort allocation involve the identification of the components of suitability and other determinants of fisher's behaviour. Observed patterns can be compared with predictions of simple models. Caddy (1975), for example, proposed a model of *proportional effort allocation* (PEA), under which the intensity of fishing effort over a season is proportional to abundance at the beginning of the fishery (usually estimated from initial *CPUE*). Observed departures from predictions made by the PEA model may result from various factors:

Figure 14.6. Behaviour of an individual fishing vessel in the Alaska weathervane scallop fishery in 1993 (see also Figure 14.8). The area shown corresponds to the north of Kodiak Island, in the Gulf of Alaska. (From Turk 2000).

- i) If there is a *density threshold* below which fishing stops.
- ii) The relation between *CPUE* and abundance is non-linear (Section 14.5.2.3).
- iii) Depletion proceeds serially, bed after bed.
- iv) Suitability has components other than *CPUE*. Location-specific factors contributing to suitability include:

Figure 14.7. *CPUE* for the sequence of hauls made along the trajectory shown in Figure 14.7. The vessel moved often during a two-month period. As the *CPUE* declined on a given bed, the vessel usually began searching for a new bed or moved to another known bed. Usually mean *CPUE* dropped to less than 2,000 kg km⁻² before the vessel abandoned each area. (From Turk 2000).

- a) Hazard factors, for example related to depth in the case of commercial divers, to exposure in the case of small vessels, and to bottom texture in the case of dredgers and trawlers.
- b) Differential costs of effort units, most often associated with distance from port.
- c) Uneven value of the catch from different beds (related to the bed-specific composition of the catch by sizes, quality grading, etc).

v) *Omniscience*: Simple models assume that fishers have *a priori* knowledge about the distribution of suitability. Such information is, however, incomplete. Uncertainty about density and location-specific factors leads to time expenditures in exploration and probing. Fishermen give some weight to experience from previous fishing seasons (“*memory*”), often “survey” the fishing grounds at the beginning of the season, and frequently alternate fishing with probing and exploration. Memory can be effectual in the short or long term. Caddy (1975) noticed that in the Georges Bank dredge scallop fishery the areas most heavily fished in previous years received more effort than expected under proportional allocation, reflecting the “inertial” effect of historical effort distribution.

vi) *Interactions* between fishing or gear units, including two forms with opposite signs: *interference* and *cooperation*.

Walters et al. (1993) extended Caddy’s PEA model to account for location-specific factors using an “attractiveness index”, and for past experience using a “memory weighting factor.”

14.4.4 The Depletion Process

Depletion, the reduction of stock size through the action of fishing, is the most immediate consequence of the fishing process. In the case of serial depletion, fishers target the densest patches available first, shifting to the next in the rank as the first are depleted. As a result, *CPUE* is not a good index of stock abundance (Section 14.5.2.3). In a simplified scenario (Orensanz et al. 1998), the relation between *CPUE* and abundance depends on the concentration profile of the stock (Section 14.3.4.2; Fig. 14.3) and the gear efficiency (Section 14.4.6). Three patterns are possible (Hilborn and Walters 1992; Orensanz et al. 1998):

- i) *Proportionality*, shown only in the case of concentration Profile Type B.
- ii) *Hyperdepletion*, in which *CPUE* declines faster than abundance. This is the case for Profile Type A: *CPUE* declines rapidly at the beginning of the season as the few high-density quadrats are depleted.
- iii) *Hyperstability*, in which *CPUE* is stable or declines more slowly than abundance. This is the case for Profile Type E (constant concentration, strictly regular spatial pattern), in which *CPUE* does not change until it suddenly drops to zero when the entire stock has been depleted. Profile Type D leads to a less extreme case of hyperstability.

The interpretation of depletion data requires caution. In the weathervane scallop fishery of Alaska, management areas are closed once a catch quota is reached. Figure 14.8 shows the trend of daily *CPUE* during a five-month fishing season. Based on their previous knowledge, fishers tend to target the densest management areas first, shifting to lower-density beds after each bed is closed. Notice that *CPUE* did not change much while each area was harvested, presumably due to hyperstability (serial depletion within each management area). If the complete series was examined without discriminating the areas, the result would be an *apparent* decline of *CPUE* due to the sequence in which the areas were harvested. Application of fishing success methods (Section 14.5.2.3) to the aggregate series would result in statistically significant parameters (initial biomass, fishing mortality), but these would be meaningless.

Figure 14.8. Behaviour of the fleet in the weathervane scallop fishery of Alaska during the summer and fall of 1993. When management areas were closed, the scallop fleet generally moved as a group from the highest producing beds to the next highest producing beds. The Yakutat, Kayak Island, and Kodiak NE area beds were closed when the upper bound of the guideline harvest range was reached, whereas the Shelikof Strait area was closed due to a significant drop in *CPUE*. All other areas were closed when the crab bycatch cap was reached. (From Turk 2000).

14.4.5 Vulnerability and Selectivity

Not all the individual scallops in a stock are equally vulnerable to fishing. We just addressed one case: scallops that are close to other scallops (i.e., live at high densities) are most likely to be caught. *Vulnerability* is determined by two families of factors, plus their interactions:

- i) *Intrinsic attributes* of the individuals, such as size, age, behaviour, phenotype or condition (e.g., physiological or reproductive condition, load of parasites and epibionts, etc).
- ii) *Contingencies* or circumstantial factors such as location, depth, local density, availability of refuges, water visibility, weather, etc.

Vulnerability of scallops varies through time. The level of activity is influenced by temperature, visibility, and fatigue. Temperature-dependent activity probably underlies the seasonal trends in catch-per-haul (highest in winter) observed in some fisheries (Dow 1962, 1969). Vulnerability can increase at night, due to reduced visibility of the gear (Olsen 1955), and after repeated dredging, due to fatigue of the scallops (Olsen 1953, 1955; Fairbridge 1953) and/or levelling off of the substrate by the gear (Hardy 1981: pp. 29–30). Swimming capability increases with age/size in *Amusium*, reducing the vulnerability of older/larger individuals (Joll and Caputi 1995).

Vulnerability of individual scallops is determined by:

- i) Fishers' decisions about where to fish (pertaining mostly to contingent factors).
- ii) Avoidance of the gear by individuals with certain attributes (e.g., largest scallops swimming away from the path of an approaching trawl).
- iii) Retention of individuals that have entered the gear, often related to the mesh size of trawls and dredges, or that are in the path of a diver, mostly related to size.

The term *selectivity* refers to the relative vulnerability as a function of some intrinsic attribute, generally size. We explicitly distinguish *global selectivity*, (resulting from the composite effects of (i) through (iii)), from *gear selectivity* (resulting from (ii) and (iii)), typically assessed experimentally (Section 14.4.6). The hierarchical components of selectivity that are actually assessed depend on the nature of the data. Most of the literature on selectivity is narrowly focused on modelling *gear* selectivity (Section 14.4.6), although factors not related to the gear can be more important in the case of scallop stocks (e.g., consider the case of “blending”, Section 14.6.2.1). Fisas (1991) described an interesting case of global selectivity for the Bay of St. Brieuc (France). The fishery targets two age groups (2+ and 3+). Before a reinforced gear design was introduced, scallops had a refuge in rocky areas. Effort in the flats targeted concentrations of age-class 2+, but was random relative to the distribution of age-class 3+.

14.4.6 Gear Performance

When fishing power is assessed experimentally, results apply only to (i) the gear utilised, (ii) the conditions prevalent at the experimental site, and (iii) the time when the experiment was conducted. “Gear” is defined here in a broad sense, eventually including a vessel and its crew (e.g., Dare et al. 1994). Components relative to effort allocation (for example ability to locate dense patches) are not considered, or included only at a very restricted spatial scale. Estimated parameters may not represent gear performance of commercial operations, as efficiency and selection are affected by the duration of the tows, towing speed, etc., which are usually standardised in experiments. Problems relative to the specificity of conditions under which experiments are conducted are well illustrated by the systematic differences between identically designed dredges or trawls towed simultaneously on port and starboard of the vessel (DuPaul et al. 1988a, b), well known to commercial fishermen. Experimental results on gear performance are most sensibly applied to the assessment of the gear and sampling units used in sampling surveys of abundance (for example the efficiency of a survey trawl or dredge). The experimental assessment of area fished, gear efficiency and selectivity are discussed below.

1. Area fished. Area swept by a dredge or trawl haul is calculated directly from the length of the haul and the width of the gear’s mouth. By contrast, it is very difficult to define the area effectively fished by a commercial diver, which in some cases allocate effort selectively even at the smallest spatial scales.

2. Efficiency. Efficiency can be affected by the nature of the bottom, operation conditions, gear leaping, gear saturation, skill of the crew, size and behaviour of the scallops, etc. (Baird and Gibson 1956; Chapman et al. 1977; Caddy 1979b; Shafee 1979; Currie and Parry 1999; etc.). CPUE increases during April-June in the Lingayen Gulf (Philippines) fishery for *Amusium pleuronectes* (del Norte et al. 1988), perhaps reflecting the influence of calm waters on gear performance. Dredges can saturate if they are towed to fullness with scallops or debris (Bourne 1965; Sanders 1966; Millar and Naidu 1991), or if the effect of “bulldozing” of sediments in front of the frame is substantial (Serchuk and Smolowitz 1980; Caddy 1989a; Iribarne et al. 1991). Efficiency is also affected by the intrinsic factors affecting vulnerability, and their seasonal variation (Section 14.4.5).

Methods that have been utilised to estimate the efficiency of scallop trawls and dredges are summarised in Table 14.2. Values estimated for dredges are often below 20%: 5–12% in the Digby fishery for *Placopecten magellanicus* (Dickie 1955), 13–25% in the British fishery for *Pecten maximus* (Chapman et al. 1977; Mason et al. 1979, 1982), 7–28% for *Chlamys varia* in the Bay of Brest (Shafee 1979), 15–21% for *Aequipecten tehuelchus* in San Matías Gulf (Iribarne et al. 1991), 44% for the “rapido” scallop dredge used in the Adriatic (Hall-Spencer et al. 1999), etc. Efficiency of all dredges vary greatly between different bottom types. A highly efficient French dredge (“Erquy” type) reached 30% on hard bottoms and 67% on soft bottoms (Buestel et al. 1985). Estimated efficiency of the Australian dredge was only 12% in the hard bottoms of Bass Strait (McLoughlin et

Table 14.2

Methods that have been utilised to estimate the efficiency of scallop trawls and dredges.

Method	Comments	Scallop examples
<i>Concurrent estimation of density (or density known), CPUE, and area fished by a unit of effort</i>		
Overlapping measurements.	Density is assessed before or after fishing in the site swept by the gear.	Buestel et al. (1985); Hall-Spencer et al. (1999)
Non-overlapping measurements, density estimated.	Non-overlapping hauls allocated randomly within each experimental site. Density in background, or background and dredged areas, can be estimated through a sample of quadrats, underwater TV, or a concurrent mark-recapture experiment.	Dickie (1955), Gruffydd (1972), Caddy (1968), Shafee (1979), Mason et al. (1982); Guguère and Brulotte (1994)
Non-overlapping measurements, density known.	Density manipulated either by placing animals in an unpopulated experimental site or by releasing marked specimens in an area where there is already some background density. In the latter case the experiment can be designed to yield a simultaneous estimate of the background density.	Dickie (1955)
Scallops “planted” randomly or regularly over the entire site.	Can be logistically complicated because large numbers of individuals may have to be released to obtain significant recaptures.	McLoughlin et al. (1991)
Scallops “planted” along parallel stripes, stretching the entire width of a rectangular experimental plot.	Fishing is conducted along parallel non-overlapping trajectories (e.g., hauls) stretching the entire length of the plot. In this way every haul encounters the same average density of released individuals, but it is not necessary to “plant” the entire plot.	Schneider (1992)
Depletion experiments		
Random or haphazard.	Compared to other methods, this setup has some advantages: it is logistically easier to implement in relatively large experimental plots, and (partly for that reason) captures more realistically the <i>modus operandi</i> of commercial fishing gear.	Iribarne et al. (1991); Currie and Parry (1999)
Systematic, covering the whole experimental plot at each sampling date.	The method is constrained to a relatively small plot size (so that the plot can be swept quickly), accurate positioning (so that there is no overlap between adjacent sweeps), and the assumption of no small-scale movements. The slope of the Leslie or DeLury equations is an estimate of efficiency.	Joll and Penn (1990)

al. 1991), but reached 38–44% on firm sand bottoms and 51–56% on soft, flat muddy bottoms of Port Phillip Bay (Currie and Parry 1999).

3. Gear selectivity. Although gear efficiency can vary in relation to many intrinsic attributes (Section 14.4.5), size is the one commonly considered. Interest in assessing the size-selectivity of fishing gear stems from the fact that “size-limits” are the most widespread tactic in the management of scallop fisheries (Section 14.6.4.1). The formal assessment of gear size-selection has received most attention in the case of trawls and dredges, largely because it is assumed that selectivity can be controlled by regulating mesh size.

The literature on scallop gear selectivity is a bit intricate, because different things are estimated with different experimental set ups. We introduce a minimal formalism to facilitate discussion. The selectivity of dredges and trawls can be partitioned into components related to capture (S_L^C) and retention (S_L^R). If the gear is size-selective, then there is some size or size interval for which efficiency (f_L) is maximal ($f_{\max}$). Then,

$$f_L = f_{\max} S_L^{C*} S_L^{R*}$$

$$S_L^C = \frac{N(L)_{\text{entering gear}}}{N(L)_{\text{path of gear}}}$$

$$S_L^R = \frac{N(L)_{\text{retained by gear}}}{N(L)_{\text{entering gear}}}$$

where $N(L)$ denotes number of scallops in the L size category, C is capture, and R retention; “*” indicates that figures are normalised so that they are within the range [0,1]. The retention component is generally related to the mesh size of the bag. Ideally, for any given mesh size there is a lower size threshold below which a negligible fraction is retained, and an upper size threshold above which virtually all individuals are retained. Methods used to estimate the selectivity of scallop trawls and dredges are summarised in Table 14.3. Selection curves for dredges and trawls take the form of sigmoid ogives (Dickie 1955; Caddy 1972; Naidu et al. 1982; Millar and Naidu 1991; Fifas and Berthou 1992, 1999). There is an extensive literature dealing with models of gear selectivity.

14.4.7 Incidental Fishing Mortality and Sub-lethal Damage

Incidental fishing mortality is very significant in many scallop fisheries, particularly dredging, because of substantial disturbance of the substrate and the associated community (Section 14.6.3.3), as well as damage to individuals left behind by the gear or culled on board and returned to the sea. This results in immediate incidental mortality, as well as various degrees of sub-lethal damage, which can eventually increase “natural” mortality.

Table 14.3

Methods used to estimate the different components of the selectivity of scallop trawls and dredges. See text (Section 3.6) for notation.

Type of observation	Component assessed	Assumptions and/or problems	Examples
Catch at size and numbers of scallops at size left in the area swept	f_L	Assumes no gear avoidance through lateral escape; poor assumption in the case of highly mobile species	
Catch at size; SFD and density of the unfished population known (seeding)	f_L	Estimation of f_{max} assumes that catchability is the same for sown and undisturbed individuals	McLoughlin et al. (1991)
Mark-recapture experiments (essentially similar to the preceding)	f_L	Estimation of f_{max} assumes that catchability is the same for tagged and untagged individuals	Dickie (1955)
SFDs of the catch and of a <i>sample</i> of scallops left in the area swept	$S_L^C S_L^R$		Fifas and Berthou (1992, 1999); Iribarne et al. (1991)
SFDs of the catch and of a sample from the unfished population	$S_L^C S_L^R$		McLoughlin et al. (1993)
Double-bag end	S_L^R		Caddy (1972b)
Simultaneous tows with different mesh	S_L^R	Same caveats as above regarding capture selectivity.	Dickie (1955); Serchuk and Smolowitz (1980); Millar and Naidu (1991); Naidu et al., (1992); Giguère and Brulotte (1994)
Samples obtained with gear rigged with different meshes; selectivity unknown for both	Only the relative efficiency of one gear relative to the other can be assessed	Results are contingent upon the composition of the population (which is unknown)	DuPaul et al. (1988a, 1988b)

(1) Factors involved. Damaging impacts include:

i) Mechanical shock, including squashing of individuals run over by dredges or passing through the mesh, damage of undersized animals discarded on board, etc. Incidental damage depends on the type of substrate. In the case of the Australian dredge it is highest in the hard bottoms of Bass Strait (60% of the catch smashed; McLoughlin et al. 1993), but very low in the sandy and muddy bottoms of Port Phillip (less than 1% of the catch damaged; Currie and Parry 1999). Shepard and Auster (1991) observed a comparable pattern in an experimental study of the commercial “rock drag” used in Maine: 25.5% of incidental damage on rocky bottoms vs. 7.7% on sand substrate.

ii) Prolonged air exposure.

iii) Turbidity and siltation. Direct observations of dredge operations showed a dense layer of liquid silt drifting close to the bottom and the scallops containing large quantities of sediment (Caddy 1989a). Using “crawl” velocity of pieces of gill tissue as an indicator of response to suspended silt, Stevens (1987) concluded that the juveniles of *Pecten novaezelandiae* may be less tolerant to suspended silt than adults, as indicated by Imai (1971) for *Patinopecten yessoensis*. High concentration and low size of suspended silt particles resulted in reduced piece crawl velocity and increased scallop mortality. Turbidity may also deplete dissolved oxygen in the water, reducing ciliar activity. The effect is more pronounced in juveniles because they cannot respire anaerobically by means of the metabolism of the crystalline style (Stevens 1987). Dredging has been prohibited in some cases when silt-sensitive spat are present on the bottom (Imai 1971).

iv) Increased exposure to predators. Active muscle adduction resulting from the escape response elicited by the gear (Dickie 1955; Caddy 1968, 1973) leads to fatigue, reducing the capability to escape from predators. Scavengers and predators have been seen on the path left by the gear feeding on damaged scallops (Caddy 1968; Chapman et al. 1977; Ramsay et al. 1998).

v) Mortality due to contamination by *Vibrio* has been associated with the very large numbers of decomposing scallops left on the sea bed after intensive dredging (McLoughlin et al. 1991).

(2) Assessment of incidental mortality requires identification of the factors and stages of the fishing process involved, and, importantly, whether short-term and/or delayed effects are under consideration. Several approaches are outlined below:

i) *Direct observation of the area swept.* Caddy (1973) used a submersible to observe lethal damage caused by dredges to sea scallops left along the tract over rough bottoms; estimated incidental mortality, 13% to 17%, was comparable to the efficiency of the dredge. By contrast, in a similar study conducted on smooth sand/mud bottoms Murawski and Serchuk (1989) observed negligible dredge-induced incidental mortality (less than 5%) in the same species. This illustrates the importance of local variation due to the nature of the substrate.

ii) *Modelling the dynamics of live bivalves and empty shells during a depletion episode.* McLoughlin et al. (1991) investigated the incidental mortality caused by the

Australian scallop dredge during a fishing season in the Bass Strait area (Tasmania). They classified the harvested population into “live”, “damaged” and “dead” (empty shell) components, and recorded the catch and *CPUE* by component for a specific fishing bed. Assuming equal catchability of all fractions, they estimated that only 12% to 22% of the initial stock in the Banks Strait ground was landed as catch, the rest being wasted as a result of dredging-induced mortality, either direct (mechanical damage) or indirect (increase of environmental stress, disease and/or predation due to the decay of dead individuals). Modelling exercises like this require some *ad-hoc* ingenuity to make the best possible use of the information available.

iii) *Correlation between apparent natural mortality and fishing effort.* Naidu (1988, 1992) suggested using estimates of apparent natural mortality based on ratios of cluckers-to-live scallops to assess incidental fishing mortality of Icelandic scallops around Newfoundland (Canada). Apparent natural mortality was higher in harvested compared to unfished beds.

iv) *Controlled survival experiments*, consisting of comparing survival of undamaged scallops (controls) with that of, depending upon the aspect of incidental mortality;

a) Individuals recovered from the area swept by the gear.

b) Individuals from the catch that would be normally discarded (culling mortality).

Experimental specimens can be kept in tanks on board, laboratory aquaria (Gruffydd 1972), or cages on the sea bottom (Murawski and Serchuk 1989). The controls can involve animals collected with non-damaging methods from unfished areas, or even individuals from the catch judged “undamaged”. Gruffydd (1972), for example, kept scallops caught with a Manx dredge in aquaria for one month, and found that the mortality of the ones that were severely damaged (broken hinge or mantle disattached) was 5 to 13 times higher than that of the undamaged group. Even animals that are apparently “undamaged”, however, can experience delayed effects and suffer a higher mortality than undisturbed individuals. Murawski and Serchuk (1989) observed a high survival rate (91% over several days) after placing sea scallops caught with a dredge into cages on bottom. This figure may be an underestimate because of possible effects of caging, which were not controlled with undisturbed scallops. This result strongly suggests that culling of undersized scallops from commercial dredge catches is a prudent conservation measure.

14.5 ASSESSMENT OF ABUNDANCE AND ITS SPATIAL DISTRIBUTION

14.5.1 Macroscale

The most important objective of scallop stock assessment at the macroscale level is to map the grounds and beds (usually subpopulations of a metapopulation), as well as other variables that are significant for habitat classification, survey design, modelling of the fishing process, etc. Caddy and Garcia (1986) presented an overview of “thematic mapping” applications to fisheries, anticipating issues and directions that became tractable after Geographic Information Systems (GIS) and spatial statistics software became widely

available (e.g., Stolyarenko 1995). The volume of geo-referenced information has exploded over the last decade. New techniques for the continuous recording of bottom properties and resources have been developed, and techniques involving underwater TV and small submersibles have been improved (Goshima and Fujiwara 1994). Recent applications to the survey of benthic resources and their habitats include acoustic bottom-type classification systems (Greenstreet et al. 1997; Kaiser et al. 1998; Hamilton et al. 1999), high-resolution sidescan sonar (McRea et al. 1999), and underwater laser line scan technology (Tracey et al. 1998). While some (like the latter) are still too costly, hydroacoustic bottom-type classification technology has been incorporated by industrial fishing vessels on both coasts of the US. In a typical example of the macro-scale level of assessment, Smith and Greenhawk (1998) used sub-bottom profiling equipment, side-scan sonar, underwater video and seafloor classification systems to assess and map oyster habitat in Chesapeake Bay. Information was geo-referenced with GPS and integrated in a GIS.

Caddy and Caroci (1999) applied a GIS system to the analysis of spatial effort allocation, which illustrates the importance of modelling processes at the appropriate scale, and the value of geo-referenced information. The study by Turk (2000) described earlier on the mapping of fishing beds of *Patinopecten caurinus* in Alaska (Section 14.4.3) is another example.

14.5.2 Mesoscale

Methods for the estimation of the abundance of a scallop bed or ground can be divided in two broad categories: (a) those based on direct sampling (survey-sampling, line-transects, mark-recapture), and (b) those based on modelling the depletion process. Information on the spatial distribution of abundance of sessile organisms is often as important as (or even more important than) knowledge of total abundance. A main difference between various methods is that some (e.g., survey-samples) can be used to assess total abundance and spatial pattern, while others address only the first aspect (e.g., simple-random-sample survey designs, mark-recapture and depletion-based methods). The spatial distribution of abundance in scallop populations has important implications for modelling and management.

14.5.2.1 Estimation of aggregated abundance: methods based on sampling

(1) Types of data used in scallop surveys. The best data are perhaps quadrat samples obtained by divers (Orensanz 1986; Ansell et al. 1991; Noel 1997; Young and Martin 1989), although this alternative can be impracticable due to logistical constraints (e.g., depth) or cost. In those cases, the option is dredge or trawl surveys, which may require a concurrent analysis of gear efficiency and selectivity (Section 14.4.6). Photo-quadrats may be valuable in many cases (e.g., Goshima and Fujiwara 1994), but are inefficient for “recessing” species or when the bottom is covered by algae, eelgrass, etc. Underwater TV and other devices used to make continuous observations along transects or stripes are discussed later in this section.

(2) *Sampling-surveys: design- vs model-based approaches.* Smith and Mohn (1987) distinguished two basic types of approaches that have been followed in the assessment of scallop stocks by direct sampling surveys:

i) “*Design-based inference*”, in which estimation of stock abundance is based on some randomised sampling design. The population is assumed to be composed of a finite number of sample units, and only the process of selection among those units is assumed random. Optimally, a sampling scheme is designed *a priori* on the basis of available information, so as to minimise the variance of the abundance estimator given logistic constraints. The most common scheme is stratified-random (Smith and Robert 1998), where strata are delimited on the basis of some auxiliary variable (depth, *CPUE*, bottom type, etc.) correlated with scallop density. Research surveys based on stratified-random schemes have been conducted annually by Canada and USA to estimate standing stock of *Placopecten magellanicus* of the Georges Bank (Mohn et al. 1987; Serchuk and Wigley 1987; Smith and Robert 1998). In the USA survey, strata are defined on the basis of depth contours, and number of tows are allotted to strata in proportion to stratum area. By contrast, in Canada contours of commercial *CPUE* are used, and sampling effort is concentrated in areas of high commercial *CPUE*.

ii) “*Model-based inference*”, in which a probability model of the distribution of abundance is fitted to the survey data. Abundance is estimated as a function of the estimated model parameters. This approach results in more precise estimators than those based on a randomised design. The caveat is that the estimates rely on the specific model used, whose selection is usually *ad hoc*. The simplest design-based approach is to fit a model to the frequency distribution of catch per tow data, which is commonly highly skewed. Several skewed probability distributions exist that can be used to fit *CPUE* data (for a review, see Elliott 1977; Smith 1988). A more complex approach is to use models that explicitly account for the spatial distribution of the variable under study. Catch per tow data are often more similar between close samples than between tows farther apart from each other. Geostatistical methods explicitly use the structure of spatial autocorrelation of the data to construct the estimators. Other models, e.g., contouring and Delaunay triangles, are implicit (Heald 1979, cited by Young and Martin 1989, p. 629; Robert et al. 1990, 1994).

Design and model based (kriging) approaches were discussed by Warren (1998); he used a scallop data set for illustration. While some proponents of model-based approaches have pointed to the fact that they produce estimates with smaller standard errors than design-based methods, Warren (1998) emphasised that variances obtained by the two methods, strictly speaking, cannot be compared, and that application of model-based methods requires subjective judgement. From the perspective of the assessment and management of sedentary resources; however, geostatistics and other model-based approaches are often a choice not because of the reduction in the variances, but because they are most suitable for mapping abundance, often more significant than the estimation of abundance itself.

The spatial allocation of survey samples defines the sampling design. Systematic grids are preferred in the case of model-based approaches (Conan 1985; Nicolajsen and Conan 1987), and simple or stratified random schemes in the case of the design-based approach. Annual surveys of *Pecten fumatus* in Port Phillip Bay (Australia) changed from a systematic to a stratified-random design in 1982 (Young and Martin 1989). Systematic grids (long disregarded because of the traditional dominance of design-based approaches) have some intuitive merits: they avoid the cost of redundant information collected when stations end up being close to each other, provide a more even coverage of the fishing bed, and are logistically easier to conduct.

Adaptive sampling (Thompson 1992; Thompson and Seber 1996), a promising development among design-based approaches, is particularly well suited for the assessment of contagiously distributed stocks, especially when information about the location of aggregations is lacking. Stolyarenko (1995), Ciocco et al. (1997) and Bechtol and Bue (1998) applied adaptive sampling designs to the assessment of scallop stocks.

(3) Line transects and stripe counts. Continuous recording of scallop density along transects has been done using submersibles (Caddy 1970, 1976; Cummins 1971), and television and photographic cameras towed on a sledge or dredge (McIntyre 1956; Cummins 1971; Holme and Barrett 1977; Franklin et al. 1980; Merrien 1980; Mason et al. 1982). Problems related to the application of these methodologies are discussed in detail in Holme (1984). The AQUAREVE ("Application QUAntitative d'un Robot Epibenthique avec controle Video d'Echantillonnage"; Thouzeau and Hily 1986) has been successfully utilised in the assessment of *Pecten maximus* in the Bay of St. Brieuc, France (Thouzeau and Lehay 1988). Efficiency has been reported to be higher than 80% under appropriate meteorological conditions (Thouzeau and Lehay 1988). Giguère and Brulotte (1994) compared the sampling performance of video and dredges with lined and unlined buckets; they concluded that video surveys are the best method for estimating size frequency distribution and density, but are time costly.

(4) Mark-recapture methods. Abundance estimation through mark-recapture methods rests on a number of assumptions, which are particularly restrictive in the case of sessile animals because (i) marked and unmarked individuals do not mix randomly after release, and (ii) effort allocation is unlikely to be random relative to the proportion of marked animals. Dickie (1955) conducted some mark-recapture experiments to estimate abundance of *Placopecten magellanicus* in the Bay of Fundy. He noticed that the non-random pattern of effort allocation, in conjunction with high mortality rate of marked animals and low reporting rates of marks in the catch (especially for empty valves), resulted in overestimation of scallop abundance. Small-scale marking experiments can be valuable for assessing movements (e.g., Stokesbury and Himmelman 1996), growth and mortality parameters (e.g., Dredge 1988) or vulnerability to fishing gear (Section 14.4.6).

14.5.2.2 Mapping

Different methods have been used for mapping scallop abundance based on research survey and/or geo-referenced catch and effort data:

(1) Designed-based methods: stratification. Standard stratified estimates yield the simplest type of “map”: all unsampled locations in the strata are assigned the strata mean. Smith and Robert (1998) discussed stratified designs using the *Placopecten magellanicus* stock from Georges Bank as an example. The design of the annual Georges Bank scallop survey is based on commercial *CPUE* during the previous months (Jamieson et al. 1981; Robert and Jamieson 1986). Several studies, however, have shown that strata and (particularly) allocation based on *CPUE* do not provide in this case gains in precision as compared to a simple random design (Mohn et al. 1987; Smith and Mohn 1987; Smith and Robert 1998). Smith and Robert (1998) proposed, alternatively, a two-tier approach in which *CPUE*-based strata are partitioned into sediment-based strata; the latter were (as a first approach) based on coarse sedimentary-ecological units defined by Thouzeau et al. (1991). As an improvement, sediment-based strata could be defined in the course of the survey using hydroacoustic bottom-type classification systems (Simon et al. 1997; Hamilton et al. 1999).

(2) Model-based methods incorporating survey design. Smith and Robert (1998) illustrated two approaches that incorporate the survey design as well as auxiliary information (e.g., sediment, depth, etc.) using also the sea scallop. Sediment type information was utilised to define strata within existing strata (post-stratification), and as factors in a simple linear model. Both methods resulted in smaller variances compared to the standard method, but in addition yielded maps of the distribution of abundance with a considerable level of spatial resolution (24 bins).

(3) Geostatistical methods have been employed in the analysis of surveys of *Placopecten magellanicus* (Conan 1985; Ecker and Heltshe 1994), *Chlamys islandica* (Nicolajsen and Conan 1987), and *Pecten maximus* (Buestel et al. 1985), among others. It must be emphasised that “kriging”, often applied in fisheries stock assessment, is just one method among others in the vast realm of geostatistics. The reader is referred to Rossi et al. (1992) for a series of interesting examples applicable to the modelling of ecological spatial dependence in scallop beds.

(4) General Additive Models (GAMs). The GAM (Hastie and Tibshirani 1990; Kaluzny 1987) is a nonparametric generalisation of multiple linear regression; both relate the dependent variable (density in this case) to possibly important covariates. In GAM, however, the covariates are assumed to affect the dependent variable through additive, unspecified (non linear) functions. Scatterplot smooths in GAM replace least square fits in regression. This method was applied by Swartzman et al. (1992) to the analysis of the spatial distribution of five flatfish species of the Bering Sea, based on survey data. The model is applicable to a variety of scallop stocks.

(5) Mapping with input from the commercial fleet. Over recent years there has been a growing appreciation of data generated by fishers themselves, which at least should complement survey data. Beyond contour mapping (Robert and Jamieson 1986), geostatistics and other methods have been proposed for mapping abundance with geo-referenced *CPUE* data, e.g., Vignaux et al. (1997). Figure 14.9 (from Turk 2000) illustrates the importance of considering information from the commercial fleet. The US National Marine Fisheries Service (NMFS) has been conducting a trawl survey of benthic and demersal sources of the eastern Bering Sea since 1976. The design is a systematic grid, with stations 20 nautical miles apart from each other. Turk (2000) mapped commercial beds of *Patinopecten yessoensis* using catch and effort information from logbook records. When the two maps (surveys and commercial beds) were superimposed, it became clear that the surveys had never hit the beds; scallop beds went undetected by the survey for *ca.* 25 years.

14.5.2.3 Methods based on modelling the depletion process

These methods are the core of stock-assessment in traditional fishery science. In their simplest form, the depletion of a closed population is modelled to estimate initial biomass and catchability. In catch-at-age methods, the most complex members of the family, the depletion of a series of year classes is tracked through time. The related catch-at-size models translate recruitment (or age composition) and growth rates into size structure to fit the available data. In most cases *CPUE* is used as an index of abundance, which presents problems in the case of sedentary organisms. These methods were developed to estimate total stock abundance; they are not informative about the spatial structure of the stock, which is at least as important as total abundance for the management of sedentary resources. These models are comprehensively covered in fishery stock assessment textbooks (e.g., Hilborn and Walters 1992). We only discuss some of their limitations, and mention scallop examples.

(1) *CPUE: limitations as an index of abundance.* *CPUE* has well-understood limitations as an index of abundance (Hilborn and Walters 1992), but those are particularly severe in the case of sedentary organisms, as discussed in Section 14.4.4. At the same time *CPUE* is extremely valuable because it is a primary determinant of the spatial allocation of fishing effort (Section 14.4.3). Departure of proportionality between *CPUE* and abundance, and consequently problems in the use of *CPUE* as an index of abundance, has several origins:

- i) *Correlation between the geographic range of the stock and stock size* implies a non-linear relation between stock size and catchability, even in homogeneous populations
- ii) *Sequential effort allocation along density gradients and serial depletion*, discussed in Sections 14.4.3 and 14.4.4, imply that abundance is not reflected by *CPUE*. This is one of the most important notions to be understood in the assessment of stocks of sedentary invertebrates.

Figure 14.9. Trawl tracks from Bering Sea surveys (1978–1997). *Dark lines*: scallops present; *light lines*: no scallops. Scallop beds were delineated with logbook data from the commercial fleet (1993–1997). (From Turk 2000).

iii) *Saturation*: handling time, gear capacity, holding capacity and some management controls (e.g., trip limits) put ceilings on *CPUE* (e.g., in the scallop fishery of the Bay of St. Brieuc, France; Fivas 1991) and result in density-dependent catchability.

iv) *Observation errors* can generate spurious density-dependence trends in catchability.

Problems [i]-[iii] reflect real and serious non-linearities in the relation between *CPUE* and density; problem [iv] can make non-linearities apparent even if they do not exist, due to difficulties with the identity or measurement of variables. All these problems are likely to be inextricably confounded in most data sets.

(2) Fishing Success Methods. Catch and effort data can be utilised to estimate initial abundance (i.e., at the beginning of the fishing season) in removal experiments, provided that the quantity of animals removed over the season (or experiment) is large enough to produce a detectable decline in abundance. *CPUE* is commonly used as an index of abundance. "Fishing success methods" are treated in detail by Ricker (1975: chapter 6) and Seber (1982: chapters 7 and 8). Two main families are of common use in fishery research: regression of *CPUE* on cumulative catch ("Leslie method") and of $\log(\text{CPUE})$ on cumulative effort ("DeLury method"). Dickie (1955), in the best-known scallop application, obtained yearly estimates of the size of the Digby stock of *Placopecten magellanicus* over 10 years (1941–1951), using a modified version of the Leslie method. Standard fishing success methods assume closed populations (no migration, recruitment or natural mortality), no competition between effort units and constant catchability. Models, however, can be modified in a number of ways for specific purposes, as is well illustrated by Dickie's (1955) pioneering study. Fishing success methods have been utilised in a variety of scallop stock assessments (Ito 1964; Joll 1987, cited by Young and Martin 1989; Wolff 1987; Turk 2000).

There is a strong warning on the use of fishing success methods in shellfish stock assessment, as *CPUE* is rarely a good index of total stock abundance (Turk 2000). They should be avoided whenever the fishermen are able to locate, relocate and selectively deplete dense patches within a fishing bed (Section 14.4.3), as best exemplified by commercial diving fisheries. Parameters estimated under those circumstances are likely to be meaningless, unless individual areas of relatively homogeneous density can be analysed independently and total stock size is estimated as the sum of the individual estimates. In dredge fisheries these methods tend to be adequate when (1) dense patches are small compared to the length of fishing tows (i.e., when they are "invisible" to fishers), and (2) the boundaries of the fishing bed are definable and data are collected at the appropriate spatial scale.

(3) Catch-at-size and catch-at-age methods. A variety of methods collectively known as "catch-at-age analyses" are central to fish stock-assessment. They provide estimates of abundance and fishing mortality by age and year from information on total catch-at-age taken over a number of years. In standard virtual population analysis (VPA; Ricker 1975), natural mortality is assumed known, as well as the terminal fishing rates producing

the latest catches from each of the cohorts involved in the analysis. This method has been applied to *Pecten maximus* (Mason et al. 1980, 1981, 1991; Fivas 1991), *Chlamys opercularis* (Mason et al. 1979) and *Placopecten magellanicus* (Kenchington et al. 1995). VPA tuned with various other indexes of abundance and fishing effort have been the standard procedure in the Georges Bank scallop stocks (Mohn et al. 1988). In the past (Mohn et al. 1984), the separable VPA (SVPA) of Pope and Shepherd (1982) was employed. A key assumption of SVPA is that fishing mortalities by age and year are a product of an age-specific factor (selectivity or partial recruitment) and a time-dependent factor, proportional to fishing effort. This reduces substantially the number of parameters needed to construct the matrix of fishing mortalities, at the expense of some loss of model flexibility. This loss of flexibility may seriously limit the applicability of the method to scallop fisheries: the separability assumption is not likely to hold when age classes are spatially segregated, specially if recruitment is highly variable and fishing effort is directed to the most abundant cohorts. When this is the case, the pattern of age-specific allocation of effort may shift over time as a result of changes in the relative abundance of the age components. Thus, time- and age-dependent effects determining fishing mortalities interact. As noticed by Mohn et al. (1984) the analysis of residuals from the fitting may point to these temporal shifts in the age-specific fishing pattern.

14.5.3 Microscale

14.5.3.1 Small-scale spatial data

The data collected to investigate the small-scale spatial distribution and abundance of scallops belong to three basic types:

i) *Counts of individuals within quadrats* are the most popular technique in the study of the spatial distribution of scallops at small scales. Spatial information about the individuals within quadrats is lost, however, and so nothing can be learned for scales below the quadrat size. Quadrat samples can be obtained directly by divers (e.g., Orensanz 1986) or remotely with underwater photography (e.g., Goshima and Fujiwara 1994). The popular book of Elliott (1977) is perhaps the best available introduction to the treatment of this type of data (see Shafee 1979, Mason et al. 1982, Thouzeau and Lehay 1988, and Goshima and Fujiwara 1994, for detailed scallop examples).

ii) *Distances between individuals and their nearest neighbours, or between points in space and the nearest individuals*, which have been rarely used in scallop studies. These data are not further considered below.

iii) *Complete maps with the coordinates of all the individuals in the study area*. A vector of data (size, age, sex, phenotype, etc.) can be associated with each individual. Maps are relatively easy to obtain (at least for small study areas) in the case of epibenthic invertebrates like scallops. Underwater photography and diving were used in two studies of giant scallops (*Placopecten magellanicus*) from Eastern Canada, in study areas ranging from 9 to 256 m² (MacDonald and Bajdik 1992; Stokesbury and Himmelman 1993). The use of quadrats is so deeply rooted that mapped data are often reduced to quadrat counts

before analysis (e.g., MacDonald and Bajdik 1992; Stokesbury and Himmelman 1993), with a consequent loss of costly information.

14.5.3.2 Spatial pattern

Three basic types of spatial pattern - random, regular and clustered - are generally recognised in ecological research. Spatial point patterns are often compared to a realisation of a completely spatially random point process. Strictly defined, *complete spatial randomness* (the “white noise” of spatial point processes) is equivalent to a *homogeneous* Poisson process; given an area A where N individuals are found, the N individuals are distributed independently (and with uniform probability) over A . Intuitively, this means that individuals are equally likely to occur anywhere within A and that they do not interact with each other, either repulsively or attractively. Complete spatial randomness characterises the absence of structure (or signal) in the data. As such, it is often the null hypothesis in statistical tests to determine whether there is spatial structure in a given point pattern. Clustered patterns (most common in nature) can reflect environmental heterogeneity (e.g., a mosaic of bottom types) or interactions among individuals (e.g., reproductive aggregations). Detection and description of spatial patterns (including their change with scale) is of significance in the estimation of abundance, the assessment of fishing strategies, and inference about ecological processes. Small-scale pattern has been investigated in scallops by means of quadrat counts and mapped data:

(1) Quadrat data: pattern at a single scale. Under complete spatial randomness the number of organisms per quadrat has a Poisson distribution, which has been observed within homogeneous habitats, e.g., as defined by sediment type (Thouzeau et al. 1991). Complete spatial randomness can be tested with a goodness-of-fit test (Elliott 1977); if rejected, and since scallops always tend to show a clustered pattern, the density frequency distribution is commonly modelled with the negative binomial distribution (e.g., Shafee 1979; Vahl 1981a, 1981b; Orensanz 1986; Thouzeau and Leahy 1988; Thouzeau 1995). The intuitive notion of aggregation entails a relation between concentration and density, used to capture pattern in indices like Lloyd’s “patchiness” and Morisita’s “index of dispersion” (Goshima and Fujiwara 1994). These indices cannot capture the complexity and multiplicity of scales of most spatial patterns. Location of quadrats within the study area and of individuals within quadrats are not considered, and consequently most of the spatial information is effectively lost.

(2) Mapped data: scale dependency of pattern and the K -function. While mean concentration at a single scale has been often used to calculate indices of aggregation, more significant aspects, like the spatial dependence between different regions of the spatial process (Cressie 1991, p. 615) or the distribution of concentration in a population at a scale of interest (“concentration profiles”, Section 14.3.4.2), have received little attention (Orensanz et al. 1998). Concentration at different scales is best captured by means of the K -function. This, the point process analog of geostatistics’ variogram, allows assessment of departures from complete spatial randomness at different spatial

scales. A scallop example is in point. MacDonald and Bajdik (1992) collected data on the individual location of sea scallops in two $15\text{ m} \times 15\text{ m}$ plots at two unfished sheltered sites (Colinet and Sunnyside) off Newfoundland (eastern Canada) (Colinet data shown in Fig. 14.10, left). The authors partitioned the study region into quadrats using various quadrat sizes, and calculated the mean/variance ratio and a transformation of mean crowding for each partition size. They concluded that the pattern was “haphazard” at Colinet (Fig. 14.10) and aggregated at Sunnyside, and speculated about the meaning of this result. The K-function analysis shows, however, that both patterns fall within the range of 100 realisations of a completely spatially random process, for all the scales about which the data are informative.

14.5.3.3 Scaling problems

Concentration analysis allows and forces focus on scale. Below we discuss some pertinent examples.

i) *Poor small-scale resolution.* Abundance data routinely collected during sampling-surveys of scallop socks (Section 14.5.2.1) are generally not informative about concentration at small scales, yet it is at these small scales that density-dependent processes governing stock dynamics are operationally effective (Section 14.3.4.3). The assessment of concentration at low scales for a whole stock, however, is a difficult proposition. One possibility is “disjoint windowing”. Stokesbury and Himmelman (1993), for example, mapped the location of individual scallops within disjoint windows (square plots) in two unharvested beds from the Baie des Chaleurs, Gulf of St. Lawrence (eastern Canada). A total of 37 9-m^2 disjoint windows were marked at haphazardly selected sites. Such data could be utilised in the analysis of concentration profiles at scales smaller than those defined by the quadrat size, across an entire bed. Pattern could be assessed *within each* of the windows by means of the K-function or related methods. Analyses of pattern within the disjoint windows, however, could not be simply combined to provide a consolidated description of pattern across the entire region without making the additional assumption that the point process is stationary across the whole region under study. Such assumption would be difficult to meet (notice, however, that concentration profiles are free of stationary assumptions). Mapped data collected from relatively small disjoint windows should not be combined, *prima facie*, to make statements about small-scale pattern across the entire region surveyed.

ii) *Poor large-scale resolution.* Problems of large-scale resolution, even though pervasive, are often less apparent. Consider the example introduced earlier (Section 14.4) about sequential depletion for different types of concentration profiles. Frequency distributions of density reported for benthic invertebrates (usually estimated with a sample of quadrats) are most often described by the negative binomial distribution (Type C in Fig. 14.3; Section 14.3.4.2). Under sequential depletion, such distributions lead to *hyperdepletion* (at least at the beginning of the harvest), as initial effort targets the small areas that concentrate much of the resource. This entails an apparent paradox: while the overwhelming majority of investigated spatial patterns would suggest hyperdepletion as the most frequent type of CPUE trajectory, *hyperstability* seems to prevail in shellfish

fisheries. Intriguingly, patterns of spatial distribution associated with hyperdepletion under strict sequential allocation (e.g., regular or quasi-regular patterns) are rarely (if ever) reported by shellfish biologists. The reason may be a mismatch between the spatial scale used in the assessment of pattern and the operational scales of the fishing process. Patterns of spatial distribution of benthic shellfish are generally analysed using small units (e.g., one- m^2 quadrats). The fishing process (including perception and harvesting) operates at larger scales, even in the case of hand-gatherers. A hypothetical diver fishing an epibenthic species will never harvest small (say one- m^2) patches in a perfect sequence of descending density, even in the unlikely case that he had a complete map of the fine-scale distribution of the resource. Pairs of small patches that rank next to each other in density will be variably (sometimes widely) separated in space. Since moving from patch to patch is costly, harvesting will depart from a simple response to small-scale pattern. If entire beds (rather than small patches) are the subject of a sequential harvest, and each bed is harvested systematically (as is often the case in diving shellfisheries), the result is hyperstability, no matter what the internal spatial pattern within each bed looks like. Surveys of spatial pattern at a small scale may be of little significance to the understanding of processes with a larger operational scale.

The distribution and pattern of concentration has generally been investigated at small scales by ecologists, and at large scales by fishery scientists. Yet, both are meaningful in the assessment of stocks of sedentary invertebrates.

Figure 14.10. Small-scale spatial pattern. Left: individual location of sea scallops in a plot at Colinet, an unfished sheltered site off Newfoundland (eastern Canada). The observed L-function (solid line, a variant of the K-function used for graphical presentation) falls within the range of 100 realisations of a completely spatially random process (dashed envelopes), for all the scales about which the data are informative. (Data from MacDonald and Bajdik 1992; figure modified from Orensanz et al. 1998).

14.6 MANAGEMENT

Fishery science and management have changed dramatically over the last ten years. The term “collapse” became a frequent key-word in the literature. A global debate took momentum on how to manage fisheries sustainably. The Precautionary Approach to fisheries management, ecosystem management, Marine Protected Areas (MPAs) and governance, rarely heard of a decade ago, took center stage. Prominent fishery collapses motivated scientific scrutiny of various hypotheses (e.g., climate *vs.* overfishing), examination of the eventual failure of the management systems involved, cross-incrimination among the various sectors in those systems (fishermen, scientists, managers, politicians), *exposes* by the press, outrage by the public, and finger-pointing by the conservation movement. It has been a most eventful decade. Thus, this Section required re-writing. Below we address aspects of the debate that pertain most immediately to the management of scallop fisheries.

14.6.1 Types of Scallop Fisheries

Scallops from shallow water environments have been harvested since pre-historic times, as shown by the presence of bay scallops (*Argopecten irradians*) in shell middens along the coasts of the eastern USA (Rhodes 1991). Yet, most scallop beds are deep enough that they were reached by fishers only after the introduction of dredges and diving. Other groups of bivalves (e.g., mussels and clams) were (world-wide) more significant to early fishing communities.

Modern scallop fisheries belong to two major groups:

i) Small-scale and artisanal operations, characterised by small vessels (usually less than 15 m long) operating in inshore waters, making daily fishing trips, and often landing at small harbours along the coast. Common methods include dredging, trawling (e.g., *Amusium* fisheries) and commercial diving. Examples are most scallop fisheries from Australia, Latin America and Europe, as well as the bay scallop (*Argopecten irradians*) fishery of eastern USA states.

ii) Large-scale industrial operations, involving larger dredgers or trawlers that make trips of several days of duration, and land catches at one or a few harbours with appropriate logistic facilities. Examples are the offshore fisheries for sea scallop (*Placopecten magellanicus*) in eastern North America, calico scallops (*Argopecten gibbus*) in the southeast USA, the Patagonic scallop (*Zygochlamys patagonica*) in Argentina and the weathervane scallop (*Patinopecten caurinus*) of Alaska.

Distinction between these two groups is significant because the most appropriate or viable management options (tactic and strategic) are different. Scallop resources, taken as a whole, are not a significant resource for traditional or subsistence fishing communities. Generally, scallop fisheries have at least some level of technology and are oriented to the commercial exploitation of a highly prized product.

14.6.2 Overfishing

An exploited population can be viewed as composed of a number of cohorts, whose individuals grow and suffer natural mortality. Recruitment of new cohorts to the exploitable stock occurs when animals become vulnerable to the fishing gear, and available and subject to fishing. The total yield obtained from a given cohort depends on its initial abundance (R), and on the mean yield (Y) obtained per recruit (Y/R). A harvest strategy based on purely biological considerations should therefore contemplate two different problems: (a) the *recruitment overfishing problem*, in which the depletion of the reproductive population results in poor recruitment, and (b) the *growth overfishing problem*, in which animals are caught when they are too small. If recruitment is assumed independent of parent stock size (at least over some range of stock sizes), fishery regulations can be aimed only at optimising the harvest from a Y/R perspective, this is, taking the best advantage of any given level of available recruitment.

14.6.2.1 Growth overfishing: yield-per-recruit (Y/R) analysis

Orensanz et al. (1991) made a general conceptual presentation of the growth overfishing problem in scallop stocks, to which we address the interested reader. Mohn (1986) reviewed some of the approaches used to conduct Y/R analysis in shellfish stocks. The Beverton and Holt (1957) formulation has been utilised to evaluate the effects of different size limits and fishing intensities on the sea scallop fishery of the Georges Bank since the 1960s (Caddy 1989a; Serchuk et al. 1979; Sinclair et al. 1985), and other stocks of *Placopecten magellanicus* (e.g., Kenchington et al. 1995), and to *Chlamys islandica* (Lanteigne et al. 1986). With different modifications, Y/R analysis has been applied to several scallop stocks: the giant scallops of the Georges Bank (Mohn et al. 1988), *Chlamys opercularis* in Scotland (Mason et al. 1979), *C. islandica* in the Gulf of St. Lawrence (Naidu et al. 1982), *Pecten maximus* in Europe (Ansell et al. 1991), *Amusium balloti* and *Pecten fumatus* in Australia (Dredge 1985; Gwyther and McShane 1988), etc. Scallop Y/R is frequently expressed in terms of mean muscle weight per recruit, although any other variable can be chosen depending on which portion of the animal is commercialised. Dao et al. (1975) used, for *Pecten maximus*, the weight of the muscle plus the gonad, which is highly valued in the French market. A Thompson-Bell analysis was conducted on a monthly base in order to account for seasonal changes in the quality of the meats.

Y/R analysis, which in its simplest form deals with single cohorts or equilibrium conditions, can be extended to address the problem of maximising the yield (or some other output) from any standing stock, whatever its age structure. This is most easily done with book-keeping algorithms, where total yield from the standing stock under a given fishing strategy results from summing up the separate contributions of the cohorts, each weighed by its relative abundance. Mohn (1986), for example, applied one such procedure to the Georges Bank scallop stock. Detection of strong recruitment pulses has often prompted *ad hoc* management recommendations, intended to delay harvesting until

recruits reach larger sizes (see for example Robert et al. 1987; Giguère and Legare 1988a, b).

Murawski and Fogarty (1984) extended the Thompson-Bell model to incorporate the spatial dimension, assuming that year-classes are segregated in space and can be managed independently. A simulation was used to evaluate different rules of spatial allocation of fishing effort. Although cohorts may be to some extent spatially segregated (and, therefore, they can be managed independently), the behaviour of the fishers may result in suboptimal harvesting of more than one cohort simultaneously. In the Georges Bank, for example, when meat-count regulations were enforced, the fishing fleet commonly targeted the densest beds, which usually correspond to young animals, and only secondarily the older, more scarce animals so as to comply with meat count regulations. This behaviour, commonly known as “blending”, results in growth overfishing, since harvesting of scallops below the stipulated meat standards is legalised (Naidu 1984; Smith and Robert 1991). The global selectivity of the fishery reflects these practices: fishing mortalities at age estimated from cohort analysis for the Georges Bank stock decline subsequent to the age groups targeted (3–4 ring scallops) (Caddy and Jamieson 1977). This contrasts markedly with the age-specific selectivity of the fishing gear, which increases monotonically with size. Mohn et al. (1984) extended the Thompson-Bell Y/R analysis to account for this (or any other) type of behaviour of the fishing fleet (see also Mohn 1986). An optimal level of (nominal) fishing effort can be computed conditioned on the assumptions about effort allocation by age. For example, fishing effort can be allocated to the different age classes in proportion to their abundance, unless meat counts fall below the enforced level.

Wolff and Mendo (2000) presented a very interesting case involving a non-stationary system: the Independencia Bay (Perú) fishery of *Argopecten purpuratus* (Sections 14.3.2.1). Population parameters differ sharply between normal and El Niño years. Besides, fishers converge to Independencia Bay from other regions during scallop booms; the increase in effort lags behind the increase in population size, with the result that the fishing force is still increasing after the stock has started to decline. The estimated optimal ages at entry for “normal” and “El Niño” years, based on a Thompson and Bell’s Y/R analysis, were 50 and 70 mm, respectively. A different legal size was recommended for the two states, given that effort cannot be realistically enforced. The size limits suggested should allow for at least one reproductive event in this short-lived species.

A modest first step to bringing the recruitment overfishing problem into Y/R analysis has been to tie the Y/R figures to some index of mean reproductive potential per recruit, and then evaluate the trade-offs between gains in yield and reproductive losses for the different harvest regimes considered. A standard index of reproductive output for scallops (Mohn et al. 1984) is the sum of age-specific mean gonad weights across all age components, each weighted by the fraction of animals surviving up to that age. Mason et al. (1981), for example, found that for *Pecten maximus* an increase in fishing effort would only slightly increase Y/R , at the expense of a considerable decrease in spawning biomass per recruit. In the *Amusium japonicum* fishery of Queensland (Australia) Dredge (1994) concluded that increasing the size limit would increase spawners per recruit marginally, while decreasing yield per recruit.

14.6.2.2 Recruitment overfishing

Many scallop fisheries have collapsed, some shortly after their onset. A collection of examples extracted from the literature is illustrative:

- i) *Aequipecten opercularis* of Spain, after the 1960s (Román 1991).
- ii) *Aequipecten tehuelchus* of San Matias Gulf in 1972 (Olivier and Capitoli 1980; Orensanz 1986), and San José Gulf in 1997 (Ciocco and Orensanz 1997) (Argentine Patagonia).
- iii) *Argopecten gibbus* off Cape Canaveral (east Florida) in 1985 (Moyer and Blake 1986).
- iv) *Patinopecten caurinus* beds off Oregon (USA) were depleted during a year of intense fishing (1981); the beds have not recovered after 20 years (Turk 2000).
- v) *Pecten fumatus* near Hobart (Tasmania) in 1908, the D'Entrecasteaux Channel (Tasmania) in the late 1940's (Fairbridge 1953) and later in 1963 (Gwyther et al. 1991, p. 838), and many fishing beds from Tasmania, Bass Strait, South Australia and New South Wales (Australia) during the mid 1980s (Gwyther et al. 1991; Young and Martin 1989; McLoughlin 1994; Young 1994; Zacharin 1994).
- vi) *Pecten jacobaeus* stocks from the Adriatic (Italy) were on the brink of commercial extinction during the early 1990s (Mattei and Pellizzato 1996).
- vii) *Pecten maximus* of Cardigan Bay (UK), in 1980 (Ansell et al. 1991, p. 732), and Málaga (Spain), in 1978 (Ansell et al., p. 735; Román 1991).
- viii) *Pecten modestus* of Cockburn Sound, West Australia (Hancock 1979; Young and Martin 1989; Young 1994).
- ix) *Pecten vogdesi* of the Gulf of California in 1973 (Félix-Pico 1991).
- x) *Pecten ziczac* of southern Brazil in 1982 (Pezzuto and Borzone 1997; Perez and Pezzuto 1998).
- xi) *Placopecten magellanicus* of Mahone Bay (Sinclair et al. 1985, p. 9) and Nantucket (Sinclair, in Kenchington et al. 1995, p. 18).

Many collapse and recovery events are not systematically documented in the technical literature, in spite of the information that they contain about the dynamics of harvested scallop stocks (Section 14.3.1.4). A comparative examination of documented cases points to several roads to recruitment overfishing:

- i) No *apparent* relationship between spawning stock and recruitment (Hancock 1973), an illusion magnified by occasional pulses of recruitment when the spawning stock is at a low level (Section 14.3.1.4). In these cases it is difficult to know if the population would have vanished even in the absence of harvest (albeit after a longer period).
- ii) Serial depletion of beds in metapopulations with low connectivity (Section 14.3.2.1), a case of hyperstability. Hyperstability is a frequent road to overfishing in sedentary resources. Although rarely investigated in scallop fisheries, it is implicit in verbal depictions of the depletion process, e.g., "[there is] little evidence of over-exploitation or depletion of grounds, perhaps masked by the ability of the fleet to locate

and move to new areas” (Ansell et al. 1991, p. 735). The best-documented case in the literature is the serial depletion of *Pecten fumatus* stocks in Australia (Young and Martin 1989, particularly their fig. 3).

iii) Depletion of source subpopulations, a hypothesis frequently advanced but difficult to substantiate.

iv) Absence of a low-density threshold at which fishing stops (“break-even point”). This occurs when scallops are fished together with species of higher value, as shrimp (Perez and Pezzuto 1998).

v) Reduction of abundance to a level at which fertilisation rate is reduced (pre-dispersal depensation), a problem that can be anticipated from changes in the concentration profile (Section 14.3.4.2). This has been suggested as a factor preventing recovery of depleted stocks of bay (Marelli et al. 1999) and sea scallops (Kenchington and Lundy 1996).

vi) Illusory high productivity due to the harvest of the biomass accumulated in a virgin stock targeted by a new fishery, documented for high-latitude long-lived species (Orensanz et al. 1998). Naidu et al. (1995, 1998) discussed the development of the Icelandic scallop (a long-lived species) in the Grand Banks of Newfoundland (eastern Canada). They predicted that at the effort levels of 1998 all known commercial aggregations could be severely depleted before significant recovery occurs.

vii) Elimination of natural refuges. Experience tells that natural refuges (Section 14.6.3.2) vanish as a result of technological improvements and changing economical incentives. The first is exemplified by the introduction of a reinforced dredge design in St. Brieu Bay, which allowed fishing in previously inaccessible rocky areas (Fifas 1991). A case of the second is the willingness of commercial divers to risk fishing at greater depths in the Argentine tehuelche scallop fishery prompted by deteriorating economic conditions during the early 1990’s (Ciocco et al., Chapter 26).

viii) Habitat destruction, principally the removal of primary settlement substrates.

ix) Economical incentives to harvest scallops smaller than the size at first spawning, a case observed in some fisheries for short-live, fast-growing tropical species (Dredge 1988; Young and Martin 1989, p. 634).

The tehuelche scallop fishery of San José Gulf provides an informative study case (Orensanz et al. 1997). During the 1970s, when divers harvested dense, shallow beds, the fishery had some features that favoured self-regulation (Orensanz 1986). Divers abandoned a fishing bed at relatively high-density thresholds (*ca.* 20 individuals m^{-2}), and selected scallops larger than the legal size (allowing for one or two spawning seasons) because smaller scallops did not have a market. Patches below the density threshold, deep beds beyond the reach of divers, and individuals below legal/commercial size provided for a significant spawning stock. In fact, the fishery proved to be sustainable for *ca.* 20 years in the virtual absence of effective regulations or enforcement. During the early 1990s, however, a new market developed for small (pre-reproductive) scallops, and a hard economic crisis led the fishers to lower their density threshold and to risk fishing in deeper waters. The fishery collapsed in 1996, remaining closed for three years (it has reopened but for small catches in recent years).

Among the roads to overfishing listed above, (1) has occasionally supported a dangerous rationale. If scallops fisheries depend upon sporadic and localised recruitment bursts, it has been reasoned, management strategies aimed at maintaining some optimal stock size for maximum long-term productivity may be futile (Fairbridge 1953, p. 37; Dredge 1986: p. 174; Perrin and Hay 1987). Gulland (pers. comm. in Hancock 1979), for example, considered that the high fecundity of scallops would result in recruitment being independent of stock size. Hancock (1979) went on to suggest that “some stocks of scallops can almost be treated as a nonrenewable resource”; harvesting strategies would be designed by comparison to “extermination”. Young (1994) summarised and criticised the (often implicit) rationales behind such propositions with relation to *Pecten fumatus*, but his synthesis is applicable to all scallop stocks:

“The economics of fishing will not reduce the stock below a minimum level that will provide sufficient breeding population to ensure recruitment and maintain the viability of the fishery. [...] Recruitment [is] unrelated to resident stock in any given bed, but derived from contiguous areas as a function of larval drift in relation to residual circulation. [Observed fluctuations in the catches] merely reflect recruitment variability which is unaffected by fishing pressure, and the stocks would be assumed to replenish from unfished areas of low density at such time as oceanic conditions are suitable to produce a ‘random’ pulse of recruits.”

In most cases, unfortunately, the relationship between stock and recruitment is difficult to specify. Under such circumstances, as Sinclair et al. (1985, p. 4) clearly put it, “since quantitative criteria to monitor [recruitment overfishing] are generally lacking, simple qualitative guidelines may have to suffice”. Preventive conservation measures that have been suggested or implemented include:

- i) A legal size that is above the size at sexual maturity (Section 14.6.4.1).
- ii) Setting apart geographic segments of a metapopulation as reproductive refuges. Knowledge about biology and oceanography are always incomplete and the results of closures are difficult to assess (Kenchington and Lundy 1996). Yet, some general criteria have been advanced for their design (Section 14.6.3.2).
- iii) Assuming that subpopulations are self-sustaining when recommending regulatory measures. Sinclair et al. (1985) tentatively concluded that “many of the scallop aggregations that support commercial fisheries are self-sustaining populations. Thus, some minimum spawning biomass must be maintained *in each fishery area* to ensure long-term harvesting potential”.
- iv) Stopping the harvest when a certain threshold density is reached, the latter perhaps tuned to the concentration-dependency of fertilisation rate (Section 14.3.4.3).
- v) Consolidation of a broodstock (Heath 1999; Marelli et al. 1999). This is an option in the case of small confined stocks in which creation of high-density “reproductive hotspots”, even if small, could produce recruitment pulses in the event of favourable conditions.

A crisis in the Bay of Fundy fishery prompted recommendations that incorporated some of these guidelines (Kenchington et al. 1995, p. 18): 20% of the Digby beds had to be closed for 10 years, closed areas should match historical nursery beds as much as possible, and a rotational program was to be considered.

14.6.2.3 A special case: recruitment fisheries

In “recruitment fisheries” all or most of the individuals that grow above legal size during the closed season (new recruits) are caught during the next fishing season. The fraction left behind by the fishery at the end of the season (usually known as “residual stock”) is often determined by the *CPUE* level at which the vessels break even in economic terms. Legal size and timing of the season are generally tuned to allow scallops to reproduce at least once in their life-times. This strategy is well suited to short-lived or quasi-semelparous species, in which most of the potential reproductive output is produced before the scallops enter the fishery. In these scenarios, in principle, there is no risk of recruitment overfishing; stock fluctuations are attributable to natural causes only. Examples include the fisheries for *Amusium balloti* of Abrolhos Island, (Joll 1989), Shark Bay (Western Australia) and Queensland (Gwyther et al. 1991). In the latter, a density of one scallop per 150 m² has been determined as the breakeven threshold. In some cases harvest has to be delayed to allow for spawning at the cost of a lower yield. This is exemplified by fast-growing tropical species like *Amusium balloti* from Queensland, in which maximum yield corresponds to an age of 6–8 months (Dredge 1988), when the scallops have not yet reproduced. Based on these calculations and on trends in *CPUE*, Dredge (1988) concluded that this stock had been recruitment overfished.

Another example is the bay scallop (*Argopecten irradians*) fishery of New England. Spawning of a cohort takes place in summer, fall or early winter (one year of age), and few individuals survive to spawn twice. Thus, if the fishery is confined to the winter there is no risk of recruitment overfishing (Belding 1910). In this fishery, scallops can be retained when they have marked the one annual growth ring that most individuals would lay down in their lifetime, an interesting alternative to a legal size (Rhodes 1991). In the calico scallop (*Argopecten gibbus*) industrial fishery off southeastern USA, also a recruitment fishery, not even a legal size or a season are enforced. The industry’s self-regulating association has agreed to limit fishing in a bed until at least 75% of the individuals exceed 38 mm; the latter has a commercial motivation but is also a conservation measure, as it allows scallops to undergo their first reproductive event (Blake and Moyer 1991).

While harvesting the post-reproductive recruits is a sensible option for short-lived, quasi-semelparous populations, the practice is troubling when longer-lived iteroparous species are turned into recruitment fisheries by excessive fishing effort. This becomes apparent when landings start to track abundance (catch being an estimate of recruitment), which generally points to a loss of potential yield (growth overfishing). This situation is exemplified by the competitive inshore fishery for sea scallops of the Bay of Fundy (Canada) and the Georges Bank US fishery, both managed through effort regulations (Section 14.6.4.4). In the latter standardised dredge surveys conducted by the National

Marine Fisheries Service generally track landings closely, indicating the high overall harvest rate and the level of dependence on incoming recruitment (Murawski et al. 2000). Beyond growth overfishing, this type of recruitment fisheries may be prone to recruitment overfishing. The decline of the *Pecten maximus* fisheries of St. Brieuc and Seine Bays (France) during the 1980s has been attributed to this kind of situation (Ansell et al. 1991; Thouzeau 1995). By contrast, in the Port Phillip Bay (southeastern Australia) fishery for *Pecten fumatus* the residual stock left after one season would not suffice to sustain the fishery during the following year, but is assumed to be the minimum needed to give rise to good recruitment (Gwyther et al. 1991).

14.6.3 Sustainability

In the search for sustainable fisheries, overfishing has repeatedly been identified as the primary problem (Botsford et al. 1997; NRC 1999). Solutions often advanced include precautionary reductions in catch levels (Section 14.6.3.1), establishment of marine reserves (Section 14.6.3.2) and ecosystem management (Section 14.6.3.3). These prescriptions, however, do not address the key failings in most fisheries systems; overfishing is a symptom of poor governance systems rather than the disease to be treated. Use and property rights, the template that shapes governance systems, are discussed in Section 14.6.3.4.

14.6.3.1 The Precautionary Approach to Fisheries Management (PAFM) and Risk Assessment (RA)

While mostly everybody in the fisheries community has an intuitive idea of what the PAFM is about, several subtly distinct interpretations coexist (Hilborn et al. 2000):

- i) Application of the Precautionary Principle, implying a reversal of the burden of proof: no fishing is allowed if the harvest policy has not been demonstrated to be sustainable (Garcia 1994).
- ii) Adoption of cautious harvest levels, guided by “biological reference points”.
- iii) An emphasis on institutional arrangements that provide for monitoring of the fishery, feedback on regulations and effective implementation (Hilborn et al. 2000).

The Precautionary Principle is significant in environmental policy, but not in fisheries management. Institutions and feedback have a prominent role in the PAFM as interpreted in a well-known technical consultation conducted by FAO (FAO 1995). Yet, the PAFM is often (and narrowly) identified with biological reference points, a result of fishery regulations articulated after the Sustainable Fisheries Act (USA), several international treaties, and other regulatory frameworks. Following interpretation (ii) of the PAFM, generic harvest control rules based on target and limit reference points have been proposed as default harvest guidelines that could perform adequately for most fisheries and circumstances (Restrepo et al. 1998). Generic harvest rules specify the desired harvest rate or catch as a function of the actual stock size; their implementation requires the use of specific harvest regulations such as a total allowable catch (TAC) or an effort

control. Management of the US fishery for sea scallops (*Placopecten magellanicus*) is a case in point. The level of fishing effort that maximises yield for a given selectivity function (F_{max}), and the equilibrium biomass (constant recruitment) reached with that effort (B_{max}), are calculated through yield-per-recruit analysis (see NEFSC 1999, for a description of the models and the estimation protocol). F_{max} and B_{max} are then used as proxies for F_{msy} and B_{msy} (biological reference points for surplus-production models), as B_{msy} is the target biomass according to the US Sustainable Fisheries Act (SFA). The stock is considered “overfished” whenever biomass drops below $B_{msy}/4$; overfishing occurs when $F > F_{msy}$, independently of biomass level. This can lead to a mind-boggling situation in which a stock that is not overfished is being overfished. The overfishing F -threshold decreases linearly to zero as biomass decreases to $B_{msy}/4$. When biomass falls in the range $[B_{msy}/4 < B < B_{msy}]$, F should be reduced to allow the stock to be rebuilt within 10 years.

Endorsement of the PAFM (however interpreted) during the 1990s gave prominence to “risk assessment” (RA), usually in the form of the calculation of the probabilistic consequences of alternative management actions (Hilborn et al. 2000). Applications of risk analyses in fisheries followed two fundamentally different approaches:

i) The first is associated with interpretation (ii) of the PAFM and the calculation of “reference points”. Given that stock size is always estimated with error, and that the relationship between management regulations and fishing mortality is always uncertain, RA is used to quantify the probability that various TACs or levels of fishing effort meet the adopted harvest rule. Examples of this approach are found in Gavaris and Sinclair (1998), Patterson (1999) and Rosenberg and Restrepo (1994).

ii) In the second approach, RA attempts to evaluate the longer-term consequences of management actions without resorting to reference points *per se*. Because management consequences generally depend on a series of actions, not just a single annual limit placed on catches or effort, future management actions need to be evaluated as a consistent set of feedback rules or management procedures used to derive the future controls. The possible outcomes of alternative management procedures are evaluated using models that are tailored to specific situations (e.g., Ianelli and Heifetz 1995; McAllister et al. 1994; Geromont et al. 1999; Parma 2001).

The first approach to RA presents several shortcomings. First, the performance of alternative management choices, or “immediate management actions” (Gavaris and Sinclair 1998), are only evaluated with respect to the adopted reference points or harvest rules and not in terms that are more meaningful to the managers and stakeholders involved with the fishery in question. Secondly, the risks of exceeding the target or limit harvest rates are evaluated for a single annual decision (the annual TAC or limit on effort) and this fails to account for the compounding effect of, say, always choosing the most liberal control within the range considered permissible (e.g., upper bound of a TAC range). Finally, discussions about the appropriateness of specific reference points or their proxies may attract more attention than the actual evaluation of the consequences of alternative actions. In other words, it is often more difficult to decide what is the appropriate value

for F_{MSY} or for B_{MSY} than it is to evaluate the possible consequences of alternative, nameless, harvest strategies.

While this is valid in general for any fishery, it is particularly relevant in the case of stocks of sedentary organisms, such as scallops, for which stock-aggregate reference points based on MSY may not be appropriate for management. Focus on MSY -related reference points may distract attention away from other strategies, e.g., spatially-explicit ones, which would be a more natural approach to controlling harvest rates.

The second approach to RA requires the use of an operating model to simulate the stock and fishery dynamics (Butterworth and Punt 1999). This is a preferred option for the *design* of stock-specific harvesting strategies, which may include different sorts of spatially-explicit regulations: territorial use rights (Section 14.6.3.4), MPAs (Section 14.6.3.2), rotation (Section 14.6.4.5), feedback from experimental management with spatial treatments and controls (Section 14.6.4.7), and localised interventions to enhance productivity (Section 14.6.4.6).

14.6.3.2 Marine Protected Areas (MPAs)

Spatial reproductive refuges, a particular form of marine protected areas (MPAs), have attracted attention as a ultimate safeguard against recruitment overfishing (NRC 2000), and may be particularly well suited to benthic resources (Orensanz and Jamieson 1998). Natural refuges, for example rocky areas where dredging is not possible (Sinclair et al. 1985, p. 9; Naidu 1991, p. 869) or depths beyond the reach of commercial divers, play a significant role in many fisheries. According to Carl Walters:

“If we look at fisheries that have been successful over the long term, the reason for their success is not to be found in assessment, learning and management models, but in the existence of a *spatial accident*, something about the spatial structure of population dynamics interacting with regulatory systems, or about the behaviour of the species and fishers, that creates a *large scale refuge* for a substantial segment of the spawning population.” (*North Pacific Symposium on Invertebrate Stock Assessment and Management*, Nanaimo, Canada, 1995; quoted by Orensanz and Jamieson 1998)

When such “natural accidents” do not exist, a priority of any sensible management plan should be to create their equivalence: reproductive refuges that are off limits to fishery operations. Reproductive refuges were implemented early in the management of bivalve stocks; the “reproductive reserves” introduced by Washington State (USA) for oysters, early in the century, are just an example. They have received renewed attention in recent years in situations that combine sedentary resources with complex spatial structure, little available information, and difficulties of enforcement. Criteria prescribed for the design of systems of reproductive refuges (Fairbridge 1953; Caddy 1989b) should attend to:

- i) The location relative to current systems and potential mechanisms for larval advection.

ii) The spatial pattern of the spawners within refuges.

iii) Areas of high scallop density that have consistently experienced good settlement over the years. Recurrence of recruitment successes (as evidenced by a persistent high density of scallops of multiple ages) must be indicative of hydrographic conditions that favour larval retention, a desirable attribute of a refuge.

In response to an unprecedented crisis in the Bay of Fundy scallop fishery in 1995, Kenchington and Lundy (1996) suggested that density had dropped to levels low enough that depensation (concentration-dependent fertilisation rate) was a concern. Following recommendations from a working group that 20% of each scallop bed should be closed to all forms of dredging during ten years, Kenchington and Lundy (1996) made specific suggestions about possible sittings of refuges based on location of persistent beds and circulation patterns (inferred mostly from drift cards).

Even small but dense refuges (reproductive “hotspots”) may prove effective in some cases, particularly in semi-closed bodies of water. Empirical evidence indicates that in broadcast spawners with external fertilisation, conveniently located reproductive “hotspots” can contribute to the replenishment or expansion of populations. Peterson et al. (1996) provided empirical support to this contention, pointing to the possibility of manipulating hotspots as part of restocking programs (Section 14.6.4.6).

In general, MPAs are part of strategic plans implemented to satisfy the complex societal agenda for the use of the maritime space, of which fisheries management objectives are just a component. Thus, the establishment of an MPA often has multiple objectives, some related to management of one or more stocks, others to conservation, others to the provision of different ecosystem services to society. In Alaska, for example, vast expanses of seabed are closed to dredging for protection of crab recruitment habitat (Turk 2000). The multiplicity of goals has led to considerable confusion regarding the implementation of MPAs. The Chilean fishing act of 1992 (LGPA, the Spanish acronym) is remarkable in that it makes a clear distinction between “marine reserves” and “marine parks”, the latter conceived for the preservation of marine biodiversity. Chile’s first reproductive reserve, La Rinconada, was implemented in the north-central coast for the conservation of the *Argopecten purpuratus* stocks.

Recent interest in scallops reproductive reserves arose as a by-product of groundfish management in the US portion of Georges Bank, where three groundfish closures were implemented in 1994. Scallop dredging was banned within the closures because of groundfish bycatch, particularly flounders (NEFSC 1999; Murawski et al. 2000). As a result, fishing effort was re-directed to the Mid-Atlantic Region; in 1998 two additional areas with substantial abundance of young scallops were closed there for three years to increase yield per recruit and spawning biomass. The biomass of sea scallops (*Placopecten magellanicus*) within the Georges Bank closed areas increased 14-fold between 1994–1998. In July, 1998, total and harvestable scallop densities (expressed as biomass) were 9 and 14 times higher in closed than in adjacent open areas.

14.6.3.3 Ecosystem management concerns

Benthic shellfish harvesting devices, unlike pelagic gear or longlines, may affect the substrate and/or the biological assemblages of harvested patches (Auster 1998; Kaiser 1998; Raloff 1996). Local recovery may be related to changes in the benthic ecosystem rather than to the removal of the target species (Caddy 1979a; Fonseca et al. 1984; Orensanz 1986). Decline in CPUE of *Pecten fumatus* in Tasmania during the late forties (Fairbridge 1953) was blamed on the “constant stirring or plowing of the bottom by the dredges.” Caddy (1979a) noticed that common overfishing criteria could not explain the declining trend observed in the Digby fishery since the mid-thirties. He suggested that habitat deterioration caused by fisheries operation could be the cause. The collapse of the fishery for *Aequipecten tehuelchus* in the NW of the San Matías Gulf in 1971 caused much concern about the ecological impact of dredging. It was estimated that each site of a fishing bed was dredged 7 times - on average - during a regular fishing season (Iribarne et al. 1991), implying a high level of disturbance. Auster et al. (1996) estimated that between 1984 and 1990 the entire US side of the Gulf of Maine was impacted annually (on average), while Georges Bank was impacted 3–4 times during the same period.

The ecological effects of dredging are, however, difficult to identify with certainty. Fairbridge (1953) for example, observed that settlement was poor in both dredged and undredged beds. Hill et al. (1999) re-sampled the benthos in 200 sites in a region of the Irish Sea that had been first sampled in 1946–1951; some of them were subject to heavy scallop dredging afterwards. Clear changes were apparent, but regardless of dredging. Laurenson et al. (1993) collected a wide array of evidence on the impact of trawling for saucer scallops off southwestern Australia. Comparison of commercially trawled and untrawled beds, combined with visual observation, indicated no significant impact on the benthic community, and short-lived physical effects on the bottom. Early experimental studies were qualitative (Caddy 1973; Butcher et al. 1981), or involved the disturbance of small experimental plots (Eleftheriou and Robertson 1992). Currie and Parry (1996) investigated changes induced by scallop dredging in the benthos of Port Phillip Bay (Australia) following a BACI (before, after, control, impact) design; disturbance mimicked commercial fishing operations in pattern and scale. Abundance of most species decreased by 20–30% after dredging, but the impact became undetectable for most of them following their next recruitment pulse; few had not yet recovered after 14 months. Changes in community structure caused by dredging were smaller than those that occur naturally between seasons or years.

Biogenic substrate (shell hash, sponge and coral bottoms, beds of epibenthic bivalves, seagrass meadows, etc) are particularly vulnerable, and their recovery from disturbance is often slow (if they recover at all). These substrates are important systemic components, often providing structural refuges or an adequate supply of primary settlement substrate, generally considered an important factor for successful scallop recruitment. Dredging or raking often removes or destroys such substrates (Auster et al. 1996), including shell hash (Caddy 1979a; Olivier and Capitoli 1980), hydroids, *Atrina* mussels (Hall-Spencer et al. 1999), and eelgrass (Belding 1910; Marshall 1947; Thayer and Stuart 1974). Catch is landed unsorted in the San Matías Gulf dredge fishery (Argentina); Olivier and Capitoli

(1980) suggested that removal of thousands of tons of shell hash (the primary settlement substrate in that ground) during the years 1968–1971 was the cause of several years of poor settlement (1971–1979). A similar concern has been recently raised with regards to the Icelandic scallop (*Chlamys islandica*) fishery (Naidu 1997). Caddy (1979a) observed that empty shells from at-sea shucking accumulated upstream and downstream the main beds in the Digby scallop beds, probably transported by tidal currents. Some components of the epifauna (mostly hydrozoans and bryozoans), known to be important substrates for primary settlement of *Placopecten*, were scarce in the fishing beds, but abundant further up the bay (Caddy 1970). He noted also (Caddy 1989a) that the removal of epifauna leaves the sediment unprotected from laminar water flow on the bottom; resulting changes in sediment composition may affect long-term productivity. Experimental studies conducted in North Carolina indicate that commercial scallop dredging and trawling for fish in shallow waters disrupt the vegetation (mostly eelgrass) and the bottom. This may impede the regrowth of the seagrass, to which scallops spat attaches. Thayer and Stuart (1974) suggested a 2-year harvest rotation period to allow for the recovery of seagrass beds.

Increased turbidity and siltation constitutes a second family of ecological side effects of scallop dredging. Black and Parry (1994) found that dredging may cause redistribution of fine sediments in Port Phillip Bay (Australia). For typical currents, suspended sediment at above natural concentrations was confined to a region within about 54 m of the dredge.

Bans on dredging were early imposed in many fisheries because of concerns about their ecological side effects. In Chile, for example, only diving has been allowed in the shellfisheries for decades. In spite of the country being one of the world's main producers of molluscs, dredges are unheard of along its 38 latitudinal degrees of coastline. Scallop dredging was banned and replaced by commercial divers in the San José Gulf (Argentina) fishery for tehuelche scallops during the early 1970s. Dredges were replaced by trawls (generally regarded as less offensive) in the *Amusium* fisheries of Shark Bay (late 1960s) and Abrolhos Bank (early 1980s) (Young and Martin 1989, p. 630).

A long-ignored problem, impacts of dredging and trawling on benthic ecosystems are a subject of much current concern (Malakoff 1998). Reflecting this change of attitude, the USA Magnuson-Stevens Act now mandates that any fisheries management plan must include a provision to minimise, to the extent practicable, adverse effects on such habitat caused by fishing, and identify other actions to encourage the conservation and enhancement of such habitat (Schmidt 1998; Watling and Norse 1998).

14.6.3.4 Strategic structures: use and property rights

Fishers, like everybody else, behave rationally: they act in their best interest given certain conditions, among them the framework created by the management system. For a strategy to work, it is necessary that the interest of the fishers coincide as much as possible with the interest of society. This is particularly true in small-scale fisheries spread over long stretches of coast, in which traditional controls (size, quotas, effort) are often unenforceable. For a system to work, fishers (and other participants in the

management system as well) should be offered the appropriate incentives. Use and/or property rights are a step in that direction. Scallop stocks are generally state property in the sense of Feeny et al. (1998). Three general forms of use rights have are found in the management systems of scallop fisheries. The natural form of fishing rights for stocks of sedentary organisms in coastal regions are co-management agreements through which *communities* are granted territorial use rights ("Territorial Use Rights for Fishers", or TURFs). Territories are difficult to demarcate and enforce in the case of offshore fishing grounds, where the obvious counterpart to communal territorial rights are *individual* rights, either to participate in the fishery or to have a certain share of effort or quota. Examples are presented below.

(1) **TURFs.** Territorial use rights over benthic resources involve a variety of formats: leases, quasi-property, property; also, they can be derived from traditional marine tenure, or introduced as a *de novo* management system. In an example of the latter, the Chilean Fisheries Act of 1992 formally introduced the right of fishing villages ("caletas") to claim tenure over portions of the seabed (AMERBs, Spanish acronym for "Areas for the Management and Exploitation of Benthic Resources"). These TURFs are granted after presentation of a base-line study and a management plan, and are effectively co-managed between fishers organisations in the caletas and the central fisheries authority. Stotz and González (1997a) described the effect of the implementation of a TURF for scallop (*Argopecten purpuratus*) exploitation by the Puerto Aldea Caleta (Tongoy Bay, Central-North Chile). The beds had been severely overexploited during the 1980s (largely through illegal fishing), and closed to legal fishing in 1988 (Stotz and González 1997a, 1997b). Following the claim of *de facto* use rights in 1991 (even before TURFs were enacted), fishers began taking care of the beds. Subsequently, average density increased six-fold over a three-year period, from 0.45 m⁻² in 1992 to more than 3 m⁻² in 1995. Although recovery of unfished beds is rapid, probably due to spawning from massive aquaculture in the bay (Section 14.3.1.4), illegal fishing continues to be intense in open-access areas. Production from fishers' organisations within the granted TURFs is likely to evolve from the exploitation of natural stocks to aquaculture (Chavez 1999).

Communal use rights have been well documented in Japanese fisheries. Following a ten-year post-war period (1943–1953) of disorderly fishing and declining yield, the drive to return to orderly catching practices resulted in the adoption of communal operation systems in about 1952 (Anonymous 1990). Ito (1964) described a case in the Okhotsk Sea Japanese scallop (*Patinopecten yessoensis*) fishery in which a strict management program (quotas, seasonal closures, minimum size, restocking, control of predators, fishers cooperative organisation) was voluntarily implemented in the Abashiri District starting in 1957, while no such a program was adopted in the neighbouring Soya District. The level of the catches was stabilised in Abashiri, in contrast to Soya, where catches plummeted to about 5% of the pre-war mean annual catch.

(2) **Limited entry.** Licensing programs, a tool for direct effort regulation (Section 14.6.4.4), have often evolved into limited entry programs, and then to making permits transferable (e.g., the scallop fisheries of southeastern Australia and Tasmania). In the

initial stages of implementation of limited entry programs (or the moratoria on fleet size that often precede them) tough decisions have always to be made about who has the right to stay, which can create much turmoil in the industry. Limited entry was introduced in the Georges Bank Canadian fishery for *Placopecten magellanicus* in 1973 (Naidu 1991), while on the US side only a permit is required. In Australia, limited entry systems were introduced in the *Pecten fumatus* fisheries of Victoria (1971) and Tasmania (1985), and in the *Amusium balloti* fisheries of Queensland (1979), Shark Bay (1985) and Abrolhos Bank (1986) (Gwyther et al. 1991). Limited entry programs are often implemented in the wake of (or as reaction to) more entrants than the resource is presumed to sustain in the long term. Attempts to downsize the fisheries from East Coast of the US in 1994 left many displaced scallop boats looking for new opportunities, Alaska being a possibility (Shirley and Kruse 1995; Turk 2000). Alaska scallop fishers reacted persuading managers (the North Pacific Fishery Management Council) to introduce a system of limited entry, which froze at 18 the number of participants (Gay 1994).

(3) Individual Transferable Quotas (ITQs). Brander and Burke (1995) compared two fisheries for sea scallops (*Placopecten magellanicus*) from Nova Scotia (eastern Canada): the inshore fishery of the Bay of Fundy and the offshore fishery of Georges Bank. The first is managed almost exclusively by traditional measures of input control, while the second has evolved to management by individual quotas in the form of “Enterprise Allocations”, or EAs. These are given to license holders who may utilise one or more vessels to catch their quota allocation, thus differing from individual quota allocation systems (IVQs, ITQs) in which quotas are allocated to individual boat licenses. The behaviour of the two fleets has been radically different. Offshore harvesters, with secure catch shares, set conservative TACs to build up biomass. This resulted in an increase of CPUE, and consequently in lower effort to catch the TAC. In the inshore fishery, on the other hand, competitive license-holders seek improvement through campaigns to increase access to other fishing areas. With neither TACs nor individual entitlements, the harvest of a good year-class over time could not be managed without complex effort controls, which the fisheries authority (DFO) cannot afford to implement. In the EA program, by contrast, each enterprise manages its quota within the annual fishing plan and has a major interest in the longer-term management of bumper year-classes, and of the fishery in general. This case shows the advantages of quasi-property management regimes. ITQs or ITEs (Individual Transferable Effort) have been advocated as an option for scallop fisheries in other industrial offshore fisheries, e.g., in the northeastern USA (Kirkley et al. 1997) and Alaska (Gay 1996).

14.6.3.5 Diversification of the resource-base

Whichever the nature of the management system, diversification of the resource-base available to a fishing fleet is a way to spread the risks associated with individual resources due to uncertainty about recruitment and markets (Hilborn et al. 2001). A multiplicity of “methiers” (“polyvalence”) is thought to be behind the relative success of the small-scale fleet of Saint-Brieuc, for which the coquille Saint-Jacques (*Pecten maximus*) is a key

element (Anonymous 1995). Institutional frameworks, however, have often pushed fisheries towards specialisation. In Canada, specialisation is a byproduct of attempts by managers to stabilise catches within individual fisheries, fleets ending up “locked” by limited entry. As is the case of most aspects of management, problems associated with specialisation can be aggravated when allocation criteria are inconsistent or ambiguous. A mixture of scallop specialists and a dual-license fleet, the latter switching between scallops and groundfish, participate in the Bay of Fundy fishery (Brander and Burke 1995; Kenchington et al. 1995). During a bonanza in 1988–1990 boats in the dual-license fleet shifted to scallop fishing, doubling the number of scallop vessels in two years. This eroded the limited entry program in the scallop fishery, removing the incentives for spreading the bonanza over a longer time horizon. Limited entry in each of the fisheries might have resulted in a more stable fishery, which should not necessarily detract from the possibility of a boat stacking licenses for different fisheries, each of them with its own cap on entry.

14.6.4 Tactics

Whichever the strategic arrangement or management system implemented, any management plan will include tactics (and “controls” associated with them), in various combinations (e.g., see Young and Martin 1989, for Australian scallop fisheries). Size limits (Section 14.6.4.1, below) form part of almost every scallop management plan. Catch (quotas), escapement (thresholds) and effort, the traditional core of fisheries regulation, have been discussed by Hilborn (1986) and Perry et al. (1999) for invertebrate fisheries, and are exemplified in Sections 14.6.4.2–14.6.4.4 with scallop cases. Stocks of sedentary organisms present the opportunity to implement other tactics, many of which are spatially explicit (Orensanz and Jamieson 1998; Perry et al. 1999). A typical example is various combinations of rotation (Section 14.6.4.5), enhancement (Section 14.6.4.6), experimental management with spatially defined treatments and controls (Section 14.6.4.7), and reproductive refuges (Section 14.6.3.2).

14.6.4.1 *Size limits*

Age-at-harvest has been rarely used as a control. As an example, bay scallops harvested in Massachusetts are required to have one annual growth ring (MacFarlane 1991). Usually, it is the size of harvested scallops that is commonly regulated by means of (i) areal/seasonal closures, (ii) absolute size limits, and/or (iii) meat counts (maximum number of meats per pound).

Legal size limits are established to allow scallops to reproduce at least once before they are caught. Minimum legal sizes are popular because they are relatively easy to enforce, their rationale is easily understood by fishers and managers (Fairbridge 1953; Gibson 1956; Imai 1971; Ito 1964; Olivier and Capitoli 1980, etc.) and, unlike TACs or effort controls, their effectiveness does not depend on having reliable assessments. In Victoria (Australia), however, minimum size regulations were abandoned in favour of

allowing the industry to determine an acceptable commercial size in order to avoid excessive handling-related damage to discarded scallops.

Because of geographic gradients in growth rate, size limits may need to be regionally adjusted. Two bays (Saint-Brieuc and Seine) produce 90–95% of the scallop (*Pecten maximus*) harvests from France. Abundance has been depressed in Seine in recent years, while the Saint-Brieuc fishery appears comparatively healthy. Growth rate and the reproductive cycle are very different between the two stocks; transplant experiments support the hypothesis that differences have a genetic basis (Section 14.3.2.2.). In Seine, scallops reach commercial size (110 mm) after their second winter, which is the age of first spawning. Thus, many of the scallops fished are pre-reproductive. In St. Brieuc, by contrast, scallops reach a smaller commercial size (102 mm) at an older age (most of the recruits have lived through their third winter). Considering that these two stocks appear to be self-sustaining and that both are now “recruitment fisheries” (Section 14.6.2.2), differences in the average number of reproductive opportunities provided by the respective size-specific harvesting regimes may explain their different success (Kiesel 1996).

Size limits are regulated through the selectivity of the fishing gear. This can be done in a number of ways:

- i) Capture characteristics of the gear, for example through spacing of teeth in front of the dredge (Imai 1971; Dupouy 1978), or development of a “search image” for size in commercial divers (Orensanz 1986);
- ii) Retention characteristics of the gear, for example through ring size in the New Bedford scallop dredge (Bourne 1965; Caddy 1971, 1972; Smolowitz 1979, in Sinclair et al. 1985) or mesh size in the “Keta-ami” scallop dredge in Japan (Imai 1971); or
- iii) Selection of the catch on board of the vessel (practised in most scallop fisheries).

Regulation of selectivity based on mesh size may be reasonable in the case of dredges with a rigid mesh (e.g., dredges built of linked rigid rings). Unfortunately, selectivity is difficult to control through mesh size with other gear designs because the mesh (no matter how large) soon gets clogged with debris and non-target organisms (Medcof 1952; Fairbridge 1953; Baird and Gibson 1956; Bourne 1965; Orensanz 1986). Culling the catch on board or landing the gross catch unsorted (Olivier and Capitoli 1980) may worsen the problem. Under such circumstances, incidental mortality (Section 14.6.6.5) and disturbance of the benthic ecosystem are more important considerations than size-selectivity.

Meat counts may be preferable to size limits when the size of the shell is not a good predictor of muscle weight (Caddy 1989a), such as when there is great variability among localities, or because of seasonal changes in condition. Meat-count regulations, however, may lead to growth overfishing, as discussed below due to the “blending” practice (Section 14.6.2.1; Naidu 1991). In the US fishery for sea scallops meat counts were abandoned in 1994 in favour of effort controls, with majority support from the industry (Griffin 1993).

14.6.4.2 Quota regulations

Quota systems have been used mostly in industrial fisheries (e.g., the eastern Canada fisheries for sea scallops), but rarely in the case of coastal, small-scale scallop fisheries. One case is the St. Brieuc fishery for *Pecten maximus*, in which a quota system was introduced in 1974 (Fifas 1991). In the *Pecten fumatus* fishery from Port Phillip Bay (Australia) tentative quotas, based on a pre-season index of abundance, are adjusted during the season through consultation between fishers and managers (Noel 1997).

14.6.4.3 Escapement regulations

Thresholds (expressed in terms of some index of abundance, e.g., *CPUE*) are a member of the constant escapement family (Hilborn 1986; Quinnn et al. 1990). In the Port Phillip Bay (Australia) the *Pecten fumatus* season is closed when catch rate falls to a prescribed level which corresponds to an estimated residual population of 60 million scallops (Gwyther 1990). The Pertuis Charentais fishery for *Pecten maximus* is also managed with *CPUE* threshold regulations (Ansell et al. 1991). Sometimes fishing becomes unprofitable below some threshold density ("break-even" point) in the absence of regulations, but this may be too low for successful renewal (e.g., the *Pecten fumatus* fisheries of Bass Strait; Young 1994). In the *Amusium balloti* fishery of Queensland (Australia), for example, the cut off point in 1986–1987 corresponded to a density of one scallop per 120–150 m² (Dredge 1988). Maintaining a certain threshold density, qualitatively related to density dependence of fertilisation rate, has been occasionally proposed as a rationale (Fairbridge 1953, p. 38; Orensanz 1986; Caddy 1989a). Thresholds and harvest rates have been occasionally combined in the form of mixed strategies. In the recovery plan for the *Argopecten purpuratus* fishery of Tongoy Bay (Chile) an exploitation rate of 10% was proposed once the stock reaches a threshold average density of 10 scallops m², while the exploitation rate during the recovery period would be only 5% (Stotz and González 1997a).

14.6.4.4 Direct effort regulations

(1) Restrictions on the efficiency of effort. Effort regulations are at least one among other components in the regulation of most managed scallop fisheries. Specific effort control measures include:

- i) Restrictions on the size and/or power of the boats (Imai 1971; Dupouy 1978; Ansell et al. 1991).
- ii) Size of gear units, and number of units (Fairbridge 1953; Dickie 1955; Dupouy 1978; Perrin and Hay 1987; Gwyther and McShane 1988; Ansell et al. 1991; Gwyther et al. 1991).
- iii) Closed seasons and temporary spatial closures (Belding 1910; Sinclair et al. 1985; Gibson 1956; Fairbridge 1953; Ito 1964; Imai 1971; Dupouy 1978; Perrin and Hay 1987, etc.).

iv) Number of fishing days, or duration of the fishing day (Dupouy 1978; Gwyther and McShane 1988; Gwyther et al. 1991; Dredge 1994). In an extreme case, the Saint-Brieuc (France) fishery for *Pecten maximus* is opened during the fishing season in two slots of ½ hr each per week (Kiesel 1996).

The most prominent example is the US fishery for sea scallops (*Placopecten magellanicus*), the largest scallop fishery in the world, where the management strategy changed in 1994 from “meat count regulation” (Section 14.6.2.1) to effort regulation (NEFSC 1999). Fishing mortality (F) is calculated in two ways: (1) from year-to-year changes in an index of abundance of pre- and post-recruits (which provides an estimate of total mortality, Z), and a ‘guesstimate’ of natural mortality (M), and (2) combining a swept-area estimate of abundance, an experimental estimate of dredge efficiency, and catch. Effort is then regulated to satisfy management goals (see Section 14.6.4.4). Assessment and management with this protocol has become questionable after the introduction of large closed areas (Section 14.6.3.2) (NEFSC 1999, pp. 111–112).

Individual limits on catch per day or per trip have been used for *Pecten maximus* in France (Ansell et al. 1991), for *Pecten fumatus* in Australia (Gwyther et al. 1991), for almeja catarina (*Argopecten circularis*) in Bahía Concepción (México; León-Carballo et al. 1991), for *Aequipecten tehuelchus* in San José Gulf (Argentina), etc. These limits are, in general, just one more way to keep a handle on effort, not a real quota system designed to achieve a desired harvest rate.

(2) **Seasons.** Closed seasons in scallop fisheries have followed a number of rationales: as one mean among others to control effort (the most common case), minimising disturbance during critical stages (for example the settlement season), allowing short-lived species to spawn at least once, because of product quality (e.g., the *Pecten fumatus* fishery of Victoria, SE Australia; Gwyther et al. 1991, p. 839) or because of red tides or other environmental conflicts. An interesting case of a faulty rationale that has been invoked from time to time is that of protection of spawning individuals in the case of iteroparous species (see Shepherd 1993, for a concise commentary).

(3) **Licensing.** Many regulated scallop fisheries have incorporated licensing as just one more option in the menu available to control effort (Dupouy 1978; Gwyther and McShane 1988). In France, for example, a cap was placed on the number of licenses issued each year in some of the locally-managed fisheries for *Pecten maximus* (Ansell et al. 1991). Sometimes, however, licensing programs have been a first step in the direction of limited entry (Section 14.6.3.4).

14.6.4.5 Rotation

Rotating fishing areas is a natural option for the management of sessile species. Indeed, rotational strategies have been developed spontaneously for many invertebrate fisheries (e.g., in the calico scallop fishery; Blake and Moyer 1991), as an option that is intuitively sustainable even in the absence of reliable stock assessments. Local

populations can be partitioned into areas or plots, each subjected to periodic pulse fishing (Munch-Petersen 1973; Sluczanowski 1984; Botsford et al. 1993). The optimal rotation problem (Clark 1976) is an analogue of *Y/R* analysis (Section 14.6.2.1), but here the control is the time interval between successive fishing pulses instead of a combination of age/size at recruitment and effort. An important conservation benefit of rotational strategies is that they may result in increased spawning biomass per recruit compared to traditional *F*-based strategies, for comparable yield levels. This advantage is exacerbated when there is substantial incidental mortality, as is the case of scallop dredge fisheries (Section 14.4.7) (Myers et al. 2001). Enforcement of spatial closures may be easier than other controls in nearshore fisheries, and also in offshore fisheries if vessels are required to have electronic location beacons (as in the US side of Georges Bank and in the offshore Argentine scallop fishery). Rotational strategies have been considered in New Zealand (Bull 1991), in the *Chlamys varia* fishery of the Rade de Brest (Ansell et al. 1991), in the sea scallop fishery of North America (Brander and Burke 1995; Kenchington et al. 1995; Myers et al. 2001), etc. The main obstacle for their implementation is opposition from other users of the seabed. Recovery of scallop abundance in areas closed to sea scallop (*Placopecten magellanicus*) dredging in Georges Bank, initially for groundfish protection, have encouraged managers to contemplate a formal rotation program in the scallop fishery (Murawski et al. 2000).

14.6.4.6 Direct interventions to enhance productivity

The management of marine [fin]fisheries relays largely upon regulations of effort, catch and minimum size. Benthic resources offer, instead, the possibility of more active interventions, destined to enhance productivity at the scale of patches of the seabed. Interventions fall into three broad groups: habitat manipulation, restocking of depleted areas, and control of predators. There is, obviously, a continuum between enhancing the productivity of natural stocks and aquaculture. One has often led to the other, as has been the case in Japan (Yamamoto 1964; Aoyama 1989). Spatially defined use rights (Section 14.6.3.4) provide incentives for investing in the enhancement of productivity, as seen in the cases of Chile and Japan.

(1) Habitat manipulation. This refers largely to the provision of primary settlement substrate. Seagrass meadows, important settlement substrate for bay scallops (Stauffer 1937; Dreyer and Castle 1941; Marshall 1947), have been decimated along the east coast of the US by different agents (anthropogenic and natural), “brown tides” being the newest among them. Replanting programs have often been implemented to palliate the effect of these catastrophes on scallop recruitment (Kelley 1988). “Shellstocking”, the practice of returning empty shells to the fishing beds, was advocated for the tehuelche scallop fishery of Patagonia (Olivier and Capitoli 1980) and for the Icelandic scallop fishery of eastern Canada (Naidu 1997).

(2) Restocking. In 1906 Belding (1910) transplanted bay scallops to an area where they had virtually disappeared. Strong settlement in the following year was attributed to the

spawn of the transplanted lot. This and other incidental observations prompted him to suggest transplants of “seed” scallops from sites exposed to winter mortality to others where survival and growth were known to be good (Belding 1910, p. 123), but this was ruled out due to high costs and political problems. Peterson et al. (1996) and Blake (1998) showed that, as anticipated by Belding (1910), restocking may help the recovery of bay scallops from many isolated estuaries along the east coast of the US and the west coast of Florida, from which they disappeared due to environmental deterioration (pollution, loss of sea grass, brown and tides, etc.).

Stocking effectively started in Japan in the thirties, and developed through successive stages (Mottet 1979; Ventilla 1982; Aoyama 1989; Kitada and Fujishima 1997): from transplants between beds (Yamamoto 1950, 1953, 1964), to the use of artificial spat collectors, to - finally - massive sowing of the seabed. The latter involves several stages: preparation of the seabed by removing predators and competitors, sowing, thinning, and fishing (Anonymous 1990; Ito 1991). The spectacular increase in settlement rate in Mutsu Bay after 1975 (Ventilla 1982; Aoyama 1989) is the most dramatic example of the effects of massive restocking (Section 14.3.1.4).

Experimental seeding programs, often combined with rotation, have been conducted for several shallow water species, including *Pecten maximus* and *Chlamys varia* in the British Islands (Buestel et al. 1985; Ansell et al. 1991; Brand et al. 1991; Heath 1999) and France (Dao and Carval 1999), *Placopecten magellanicus* in eastern Canada (Cliche et al. 1994; Barbeau et al. 1996; Hatcher et al. 1996), *Pecten fumatus* in Australia (Cropp 1986; Perrin and Hay 1987: p. 7), *Pecten meridionalis* in New Zealand (Bull 1991), *Argopecten irradians* along the east coast of the US (Middleton 1983; Goldberg et al. 1999), and *A. purpuratus* in Chile (Munita 1988). Restocking, however, is still an unrealistic option in the management of many fisheries (see for example Dredge 1988: p. 239). A major problem with restocking/rotation programs are legal limitations to closing of beds (Bull 1991; Ansell et al. 1991), which is of course not the case in systems structured around territorial use rights (Section 14.6.3.4). Managers and fishers from Iles-de-la-Madeleine (Quebec) are collaborating since 1993 in a unique large-scale restocking program (“REPERE”); 1.7 million juveniles were seeded, 77,000 of them tagged. Fishing was closed initially, and reopened in 1997 (Nadeau and Cliche 1997, 1999; Cliche and Giguère 1999; Nadeau et al. 1999). Annual landings from the Bay of Brest fishery (*Pecten maximus*) have increased from 50 tons during the early 1980s to 200 tons in recent years as a result of the combined rotational harvest of natural and seeded beds (Dao and Carval 1999).

(3) Control of Predators. Elimination of predators has been frequently recommended, sometimes even enforced, as part of scallop management programs (Belding 1910; Ito 1964; Golikov and Scarlato 1970). Starfish have been the most frequent target. Active control techniques, like applications of calcium hydroxide to kill starfish (Arima et al. 1975), have been tried in some cases. Most frequently, however, only predators caught in the fishing gear are destroyed. Fishermen in the Okostsk Sea Japanese fishery are sometimes required to retain and land starfish (Ito 1964). Abundance of starfish is assessed during the scallop surveys, allowing an estimate of the effect of removal. Every

year fishermen killed 1.5–5.0% of the starfish present on the beds (Ito 1964). Control measures can be more indirect, as was the case with the prohibition of cleaning the catch at sea in Tasmania (Fairbridge 1953), in the belief that throwing scallop waste on the beds would enhance starfish populations. The effect of predator removal on managed scallop stocks remains – to our best knowledge – unassessed.

14.6.4.7 Experimental management

Benthic resources offer the opportunity to implement experimental management programs with spatially distributed treatments and controls. One limitation in the case of forms with pelagic larvae is that only measures associated with pre-dispersal biological may be amenable to this type of experimentation, as larvae generated in an experimental plot settle elsewhere. Yet, Peterson et al. (1996) showed that experiments can be informative even in the case of measures relative to pre-dispersal processes (enhancement of the spawning stock in their case). In most cases, however, experimentation has dealt with control of predators, the secondary effects of harvesting techniques, density-dependence of post-settlement growth and mortality, etc.

Ito (1964) described a situation in the Okhotsk Sea fishery that came close to experimentation with the entire management system, following a ten-year post-war period (1943–1953) of disorderly fishing and declining yield. A strict management program (quotas, seasonal closures, minimum size, restocking, control of predators, cooperative organisation of the fishers) was voluntarily implemented in the Abashiri District starting in 1957, while no such a program was adopted in the neighbouring Soya District. The level of the catches was stabilised in Abashiri, in contrast to Soya, where catches plummeted to about 5% of the pre-war mean annual catch.

ACKNOWLEDGMENTS

We dedicate this contribution to our colleague and friend John F. Caddy, always the first to think in the right direction.

ENDNOTES

¹ The concept was introduced in marine population dynamics simultaneously in 1986 by Roughgarden and Iwasa (a model inspired by barnacles) and by Orensanz (a scallop study), who used the slightly different term “megapopulation”. In subsequent years the term “metapopulation” became the standard in population dynamics. The two are equivalent, at least in this context.

² By “sedentary” we do not mean sessile or immobile. Rather, we indicate that the movements of post-settlers (benthic juvenile and adult scallops) have a small spatial scale compared to processes relevant to large-scale dynamics (e.g., larval dispersal and fleet behaviour).

³ In the first edition of this book we introduced the word “connectedness” which (as our spell-check now indicates) is not part of the English language. “Connectivity”, an appropriate alternative with the same meaning, has become the standard term (e.g., Roberts 1997).

⁴ Throughout this chapter we use the term “aggregate” (as in “aggregate abundance”) in reference to an entire metapopulation or subpopulation, with no consideration of its internal spatial structure.

⁵ “Recruitment” is used here in the sense of recruitment to the fishable stock. In benthic ecology the word is often used to denote a combination of settlement and early post-larval stages.

⁶ The homogeneity assumption is also met if the individuals of the harvested population are mobile and redistribute themselves after a fishing operation. This is never the case for scallops.

Chapter 15

Fisheries Sea Scallop, *Placopecten magellanicus*

K. S. Naidu[†] and G. Robert

15.1 INTRODUCTION

From an economic viewpoint, the sea scallop, *Placopecten magellanicus* (also called giant scallop, smooth scallop, ocean scallop or Atlantic deep sea scallop) is one of the most important pectinid species in the world. Between 1990 and 1999, it alone accounted for some 28% of the mean annual global production of all scallop species combined (Table 15.1). Sporadic booms in natural production associated with temporal fluctuations in abundance in some species (e.g., calico scallop) and manipulated production through enhancement in some others, particularly the Japanese scallop, *Patinopecten yessoensis*, have in recent years relegated sea scallop landings to a seemingly secondary role, spuriously depressing the sea scallop contribution to world tonnage. Increasingly it has become difficult to distinguish as distinct and separate scallop landings based on wild populations (capture fisheries) from those involving production involving some form of manipulation (e.g., sea ranching).

The Atlantic sea scallop is a relatively large mollusc commonly reaching sizes between 10–15 cm and frequently beyond. While large as contrasted with several other scallop species, the implied gigantism is not always characterised by unusual or disproportionate shell size. The largest sea scallop ever recorded measured 211 mm (shell height, tangential dorso-ventral measurement), a size a little larger than the previous recorded of 208 mm (Norton 1931) and had an adductor muscle (meat) weight of 231 g (0.51 lb.) (Naidu, unpubl.). Rock scallops, for example, are better endowed with shell heights approaching 250 mm (Hennick, cited in Kaiser 1986). Maximum age recorded for sea scallops is 29 years (Naidu, unpubl.). The shell of the sea scallop is almost circular in outline with symmetrical wings at the hinge (Fig. 15.1). Whereas the lower right valve is white, flat and smooth, the left valve is usually light to pale brown, convex and delicately ribbed. Occasionally, both shell valves are white. Concentric rings on the delicately ribbed surface of the left valve have been verified to be annual (Stevenson and Dickie 1954; Posgay 1962; Naidu 1969) and are commonly used for age determinations. Oxygen isotope records have also confirmed that growth lines are in fact annual events, consistent with biological interpretation (Tan et al. 1988). Hurley et al. (1987) have shown that the number of growth lines in laboratory reared post-larval shells is related to the actual age in days. Growth rings are especially pronounced in northern shallow-water populations (Naidu 1975). Repeated encounters with fishing gear in heavily fished aggregations and the haphazard deposition of shock rings makes interpretation of annual growth rings

Table 15.1

¹ modified from Naidu et al. (2001).

Figure 15.1. Left and right valves from a 5-year old sea scallop showing prominent concentric growth rings. The right valve is flatter and usually lighter in colour than the left valve.

sometimes difficult and frequently impossible. Under these circumstances, it may be necessary to utilise growth bands on the resilium (Merrill et al. 1966).

15.2 DISTRIBUTION

Confined to the Northwest Atlantic, the sea scallop has a geographical range from the north shore of the Gulf of St. Lawrence (Squires 1962) to Cape Hatteras, North Carolina (Posgay 1957a, Fig. 15.2). Although primarily a continental shelf species, and found usually in depths ranging from about 10–100 m (5–55 fm), it may be found in shallow water just below low tide (Verrill and Smith 1873; Read 1967). There is even a record of it occurring intertidally in the Gulf of Maine (MacKenzie 1979) but this must be considered anomalous and needs verification. Farther south, because it is restricted to areas with maximum water temperatures less than about 20°C, they are usually found at depths exceeding 55 m (30 fm). Merrill (1959) extends its bathymetric range down to 384 m (210 fm). As an environmental variable, depth has a pervasive influence on nearly all aspects of the growth and biology of the species (Posgay and Merrill 1979; Shumway and Schick 1987; Schick et al. 1988).

Sea scallop beds of sufficient extent and density to support commercial fisheries occur from Virginia Capes (latitude 36°50'N) to Port au Port Bay, Newfoundland, Canada (latitude 48°40'N). Offshore, sea scallops have been exploited commercially on Georges Bank, the Mid-Atlantic Shelf, Browns Bank, German Bank, Lurcher Shoals, Grand

Figure 15.2. Principal sea scallop fishing grounds.

Manan, around Sable Island, Middle Ground, Banquereau Bank, and on St. Pierre Bank (Fig. 15.2). Georges Bank consistently rates as the world's largest producer of scallop. The Bay of Fundy (especially off Digby) and Gulf of Maine also have had a long history of production. For Canada, the Bay of Fundy landings have been second to Georges Bank except for very recently (Table 15.2). In the center of its range (Georges Bank and Middle Atlantic Shelf), scallops have been quite successful and have withstood moderate to heavy exploitation. The Mid-Atlantic area off Long Island and New Jersey (New York Bight) and Delmarva and Virginia-North Carolina regions has become more important in

recent years sometimes contributing to more than half of the USA total scallop production. The recent closure of areas on Georges Bank has also contributed to the rise for the Mid-Atlantic area. In the Gulf of Maine, the majority of catches come from inshore U.S. territorial waters. Georges Bank where most of the offshore effort is directed constitutes the world's largest single natural scallop resource (Caddy 1989). Scallop production on Georges Bank has been attributed to the presence of a large gyre which forms during the summer and later helps to retain planktonic scallop larvae within the area until they are ready to metamorphose and settle to the sea bottom (Larsen and Lee 1978). Towards the extremes of their range sea scallops generally have been less successful and have not withstood continued heavy exploitation (Dickie and Medcof 1963). Fisheries in fringe areas such as the northeast coast of the United States (Serchuk et al. 1979) and St. Pierre Bank (Naidu et al. 1983b) typically are characterised by a disproportionate dependence on sporadic recruitment of a single or a few intermittent and, sometimes, well-spaced year-classes. Consequently, in fringe areas, fisheries must cope with wide and, sometimes, catastrophic temporal fluctuations.

As in most scallop fisheries, sea scallop recruitment, even in the center of its range frequently is irregular and pose undue problems to an industry that is typically overcapitalised. Even in industries that are no longer overcapitalised (Canadian deep sea fleet), the irregular recruitment plays havoc in the supply and demand sides of the market. In some other areas such as the Bay of Fundy (Caddy 1979; Dadswell et al. 1984; Robert et al. 1984), there is evidence of cyclicity in production which appears to be associated with periodic tidal phenomena. These departures from "steady-state" have wide-ranging implications for the orderly development and judicious management of scallop fisheries.

Table 15.2

Relative (percent) contribution of recent sea scallop landings from principal scallop producing areas of Northwest Atlantic (Canada).

Year	Georges Bank 5Z	St. Pierre Bank 3P	Sable Island and Western Banks 4W	Browns Bank 4Xo,p	German/ Lurcher 4Xq	Bay of Fundy and approaches 4Xr,s, 5Y

15.3 HISTORY OF FISHERY

The sea scallop is the most important commercial bivalve in North America. In the United States, the fishery is over 100 years old (Table 15.3), and second in value only to the American lobster. The fishery developed inshore off New England, but was of little commercial significance until 1883, when several scallop beds near Mt. Desert Island, Maine were discovered (Smith 1891; Premetz and Snow 1953) (Fig. 15.2). Ports in Maine were the leading producers. Landings between 1889 and 1924 were characterised by considerable fluctuations with maximum landings recorded in 1905 (195 t meats). With the discovery of scallop beds off Long Island in the early 1920's, Middle Atlantic ports temporarily became the center of U.S. scallop operations. New England regained leadership in sea scallop production in the mid 1930's with the discovery of offshore scallop beds on Georges Bank (O'Brien 1961). New Bedford, Mass., soon emerged and continues to be the leading U.S. port for the sea scallop industry. By the early 1930's the U.S. fishery had already spread offshore to Georges Bank. Between 1975 and 1979, more than 50% of the total U.S. scallop production has been from the middle Atlantic Shelf (Anonymous 1977).

In Canada, first landings recorded in the fisheries statistics of Canada were made in 1886 when 300 dozen were sold from Lunenburg County (Bourne 1964). A fishery developed along the southwest coast of New Brunswick in 1889. The Digby scallop beds were discovered in 1920 and the fishery there expanded rapidly into the Bay of Fundy. Landings here have fluctuated widely and reached a record of 4,600 t meats in 1989. The Digby fishery also initiated the practice of shucking scallops at sea. While minor fisheries for the mollusc were reported inshore elsewhere in the Maritimes, including the Gulf of St. Lawrence, the Digby fishery continued to be the mainstay of the Canadian fishery until 1945 when a long-standing interest in the offshore banks began to materialise. Encouraged by the relative success of the initial forays offshore, Canadian authorities, both public and private, conducted systematic explorations off the coast of Nova Scotia and the vast apron of shelf to the south and southeast of Newfoundland commonly referred to as the Grand Banks of Newfoundland (Dickie and Chiasson 1955; Somerville and Dickie 1957; MacPhail and Muggah 1965; Rowell et al. 1966a, 1966b). Beds of sea scallops on St. Pierre Bank, off the south coast of Newfoundland (Fig. 15.2), for example, were discovered during one such exploratory mission in 1953. Many of the earlier surveys were not fully documented (Caddy and Chandler 1968). Industry frequently adopted a proprietorial attitude towards newly discovered scallop beds and were loathe to publicise new finds. By 1954, landings by the Canadian offshore fleet surpassed those of the inshore fleet for the first time (Bourne 1964). Canadian scallop landings nearly doubled to 1044 t meats within six years after a concerted attempt had begun in 1956 to prosecute stocks offshore. By 1965, 75 percent of the annual removals from Georges Bank was taken by the Canadian fleet. The Canadian effort on Georges Bank was primarily focused on the Northern Edge and Peak, which encompass some of the most productive areas of the Bank. From the outset the Canadian sea scallop industry was and continues to be centered in the Province of Nova Scotia.

Table 15.3

Sea scallop landings (metric tons, meats) from the Northwest Atlantic, 1887–1998.

Year	USA ¹ (t, meats)	Year	USA ¹ (t, meats)	Can ² (t, meats)	Total (t, meats)

¹ U.S.A. landings from Anon.(1989), F. M. Serchuk (pers. comm.) and NAFO Statistical Bulletins.² Canadian landings modified from Anon.(1989), and NAFO Statistical Bulletins and Naidu et al. (2001).

With the fuller development of the Canadian and U.S. fleet after World War II, Georges Bank saw a dramatic increase in annual landings and quickly became established as the world's largest producer of scallops. Concomitant with the success of the then competitive Georges Bank fishery and the discovery of new beds elsewhere along the Atlantic seaboard came inevitable overcapitalisation. Frequently, industry is unable to respond in sympathy to the downturns associated with the extreme dynamism exhibited. As in other fisheries, correction to overcapitalisation is never as rapid as the initial response to a perceived new opportunity and is nearly always fraught with difficulty (Caddy and Gulland 1983). Industry generally has been slow to respond to these fluctuations in abundance.

The shared jurisdiction of this resource by Canada and the U.S. prior to ratification of the Convention for the Law of the Sea (October 1984) necessitated a joint management regime under the auspices of the International Commission for the Northwest Atlantic Fisheries (ICNAF). Attempts to increase yield per recruit by controlling the size of recruitment by imposing a size limit, in the case of scallops a meat count (number of meats/unit weight), were met with only partial success. The meat count was too high to be effective. A competitive fishery, although Canada had limited entry since 1973, led to very high levels of fishing effort and fleet overcapacity on both sides. As a consequence of the World Court decision on the fisheries jurisdiction of the United States and Canada on Georges Bank, the offshore fleets became restricted to their respective national zones (Fig. 15.2). Canada and the United States continue to be the sole participants of this lucrative fishery.

With the advent of the 200-mile Fisheries Conservation Zone in U.S. waters, the New England and mid-Atlantic Fisheries Management Councils developed and implemented the Sea Scallop Fisheries Management Plan (FMP) to regulate the fishery. Under the FMP, sea scallop fisheries for the Gulf of Maine, Georges Bank, and the mid-Atlantic are managed to address concerns of growth and recruitment overfishing via biological reference points such as yield per recruit. Over the last 25 years, there have been 2 periods of landings over 100,000 metric tons (round weight), the late 1970's and from 1987 to 1992.

Landings in the latter period peaked near 150,000 metric tons in 1990 (Table 15.4). Between the 2 peaks, most of the 1980's produced considerably less with a minimum slightly over 50,000 metric tons in 1985. After the last peak, annual landings have declined to lower values (1997–1998) than the minimum encountered during the 1980's. On Georges Bank landings peaked in 1990 and decreased thereafter due to poor stock conditions and area closures. In the mid-Atlantic region, landings peaked in 1989 and then fluctuated around a lower average estimate in later years. In the U.S. Gulf of Maine the 1998 landings reached a record high; there might have been problems in assigning catches to fishing areas.

After the jurisdiction for fisheries on Georges Bank had been settled by the World Court in October 1984, the Canadian offshore scallop industry focused on stock rehabilitation through better harvesting of the resource. Important reductions in fishing effort and the adoption of a new management regime were to rebuild the stock while optimising the yield, stabilise catches from year to year, and rationalise the fleet.

http://www.dfo-mpo.gc.ca/communic/statistics/landings/land_e.htm

Landings from Georges Bank, the area contributing the most, peaked in 1987 and in 1992–93 at over 50,000 metric tons. Landings have been on a declining trend since the last peak. The range of landing figures since 1986 (16,500–56,500 metric tons) when the management plan was significantly altered is more narrow than the pre-1986 period when the fishery was competitive. Other offshore areas on the Scotian Shelf (German Bank, Browns Bank, Sable Island and Western Banks) may be exploited on a somewhat sustainable basis but do not produce landings comparable to Georges Bank (range of 1,700 to 17,000 metric tons). However, the same strict management measures generate comparable catch rates (Table 15.5). Less productive areas like St. Pierre Bank are exploited occasionally with a maximum under 1,500 metric tons.

15.4 POPULATION BIOLOGY

Unambiguous identification and separation of stocks within this species has been problematical as has been the assumption, sometimes justifiable, that fisheries are based on self-sustaining megapopulations (Caddy 1975; Orensanz 1986). Although phenotypic differences abound throughout its geographic range, genetic distances appear to be relatively small. Overall, the evidence for the existence of discrete stock units is not persuasive (Zouros and Gartner-Kepkay 1985; Volckaert et al. 1990) and suggests sufficient larval exchange between adjacent areas even if sometimes only unidirectional (Squires 1962; Naidu and Anderson 1984). Conceptually, it is tempting to reconcile the larval phase in this relatively sedentary species with its adaptive function of dispersal. A recent review (Sinclair et al. 1985) of important scallop fisheries for which long-term data are available, on the other hand, suggest that the main fishable concentrations are associated with strong tidal circulations (Tremblay and Sinclair 1988) or located in areas of persistent gyres (Caddy 1979; Posgay 1979a). Sinclair et al. (1985) argue that self-sustaining characteristics are borne out by the persistence in widely separated areas of scallop aggregations. But this view does not easily explain the persistence of “terminal”

scallop populations with reduced reproductive output (estimated gamete production) (MacDonald and Thompson 1985b, 1986a) and reduced reproductive effort (proportion of non-respired assimilated energy allocated to reproduction (MacDonald et al. 1987; Robert and Lundy 1985). Knowledge of the source(s) of recruitment for a given aggregation and the relative larval contribution from within and or without is important to a clearer understanding of the overall population dynamics of that aggregation. Knowledge is quite limited in this area. Modelling exercises of scallop larval transport on Georges Bank support the theory of larval retention where gyral circulation exists (Lewis et al. 1999). The advent of remotely sensed satellite data to delineate ocean features such as thermal fronts could illustrate their influence on scallop settlement.

In exploited populations, it is also necessary to be concerned with important concepts of overfishing (recruitment overfishing versus growth overfishing). Allegations of recruitment overfishing notwithstanding, empirical data supporting its possible occurrence in sea scallops is weak, if not non-existent. Such data that are available seem to indicate that reproductive success in this highly fecund species is not wholly constrained by a low biomass. A healthy ten-year-old female may release up to 90–95 million eggs during a single spawning season (MacDonald 1984). A plot of age 4+ biomass against recruits (lagged by three years) for Georges Bank, for example, show that above-average recruitment occurred even when biomass was at historically low levels during the 1970's (Mohn et al. 1987). The same type of data with more recent information, including the 1997 biomass, confirmed that low or high levels of spawning stock biomass do not necessarily relate to high recruitment. It would appear that moderate biomass levels produce higher recruitment (Robert et al. 2000). The apparent lack of a linear stock recruit relationship suggests that conventional finfish assessment models may not be easily extrapolated to sea scallops. Refugia of unexploitable scallops, either at very low densities and or inaccessible to traditional fishing gear must necessarily safeguard the self-reproducing capacity of the megapopulation. This would be the case particularly in an area where water circulation is conducive to retaining the otherwise fugitive larvae within a given area for at least as long for them to settle on suitable substrates and complete metamorphosis (approx. 1–2 months) (Culliney 1974; Larsen and Lee 1978). As such, recruitment overfishing is seldom, if ever, specifically addressed in the protection and husbanding of the resource. Even if not completely understood, the apparent resilience to recovery in this species appears to be fairly widespread however. Also, the spawning potential is implicitly safeguarded by regulations which seek to maximise yield per recruit (older individuals contribute little to somatic production but a great deal to reproductive output (MacDonald and Thompson 1986b)). The authors are not aware of an exploited population of sea scallops with a significant production history whose imminent biological collapse has been somehow prevented through regulation of fishing activity or one that has not self-rehabilitated from near commercial extinction. Ongoing investigations into the culture and resource enhancement of this species in Newfoundland have shown that concentrations of spat on artificial substrates are sometimes disproportionately high (Naidu et al. 1983a) and not commensurate with spawning scallop biomass in the area from where seed were collected. Similarly, in Port au Port Bay, Newfoundland settlement of up to 6,500 seed/collector ($x = 4,000$) has been recorded

even when mean annual production during the five years preceding was only 7.2 t meats (M. Lanteigne, pers. comm. [Science Branch, Department of Fisheries and Oceans, Moncton, New Brunswick, Canada E1C 9B6]). Until recently, research on the sea scallop has been confined primarily to the adult phase. The dearth of information concerning larval biology of the species in the open sea remains a conspicuous gap in our knowledge of the life history of this species (see Tremblay et al. 1987; Tremblay and Sinclair 1988). Field studies on spawning, larval distribution, and spat settlement now have become major concerns in Canada (Naidu and Scaplen 1979; Sinclair et al. 1985; Naidu et al. 1989). The question of whether scallop aggregations are self-sustaining has not been unequivocally resolved. Neither has a relationship been shown to exist between source of recruitment for a given scallop aggregation and the degree of temporal stability of that aggregation.

On the basis of historical patterns of production, Caddy and Gulland (1983) attempted to broadly classify fisheries as being a) steady, b) cyclical, c) irregular, and d) spasmodic. They proposed that approaches to management of fish stocks must recognise this departure from the often-assumed equilibrium or steady state conditions. For sea scallops it is apparent that while the biomass in each persistent self-reproducing aggregation has shown considerable fluctuations, not all of which are ascribable to fishing, the order of magnitude of average population size has remained more or less constant (Sinclair et al. 1985). On the basis of this observation, Caddy (1989) concludes that sea scallop fisheries are better described as cyclical (Caddy 1979; Dadswell et al. 1984; Robert et al. 1984), irregular or spasmodic, as suggested for populations in the northern (Naidu and Cahill 1984) and southern (Serchuk et al. 1979) limits of their distribution range. Four strong year-classes, those of 1957, 1972, 1977 and 1982 for example, have produced major peaks in landings of the Georges Bank fishery prior to 1990. The 1972 year-class resulted in peak landings of nearly 18,000 t in each of 1977 and 1978. Consequently, optimising the yield per recruit has been a major management objective of this recruitment-driven fishery, at least over the short term. In fact, more recent strong year-classes are not directly reflected in peak annual landings of the Canadian deep sea fleet because quota management spreads the benefits of an abundant year-class over 2–3 years.

15.5 GROWTH AND YIELD PER RECRUIT

Sea scallop growth rates are highly variable, depending on location. While much data on sea scallop growth have been assembled over the years, much remain in a form not amenable to a formal publication (see for example, Posgay and Merrill 1979). Growth rates calculated for various aggregations are reported usually in the form of the von Bertalanffy growth equation. Considerable differences in the growth pattern of scallops is evident for different populations of scallops (Table 15.6). Naidu (1969) reported that scallops from more northern latitudes generally have larger H_{∞} values; conversely, K values, generally, are smaller. Posgay (1953) reported that scallops living in an area with a narrow temperature range near 10°C exhibited the best growth. Growth rates have been shown to be negatively correlated to a combination of temperature and food availability with low temperature and low food levels producing the slowest growing scallops

(MacDonald and Thompson 1985a). Furthermore, under the same general conditions of temperature and food availability in the Bay of Fundy, Smith et al. (2000) have found growth-rates to be spatially specific. Length-weight relationship of sea scallop populations have been described by numerous authors (e.g., Haynes 1966; Worms and Davidson 1986b; Naidu et al. 1983b; Naidu and Cahill 1984; Robert and Lundy 1987). While sexual maturity may be attained as early as age 1, initial spawning does not occur until the second year after the deposition of the first growth ring when scallops typically are between 23–75 mm (Naidu 1970; Posgay 1979b). Fecundity of the younger age-groups contributes little to total egg production however (MacDonald and Thompson 1986b).

Knowledge of the age structure of populations, growth rate and longevity are essential for effective management of the fishery. Aspects of the general population dynamics of scallop species are considered in Chapter 14. Recently, Caddy (1989) has succinctly summarised some of the approaches utilised in the assessment of scallop fisheries with particular reference to the sea scallop, *Placopecten magellanicus*. The assumption that the main scallop fisheries are self-sustaining megapopulations (Orensanz 1986) is reasonable and could be the basis, as it frequently is, for management measures instituted for their rational exploitation (Caddy 1989). Within each superpopulation gradients of scallop density exist, often culminating in a patch containing scallops of above-average density. A fishing ground consists of areas where scallops occur in high densities (beds), interspersed with areas where densities are as low as 1/40 of that in the center of the bed (Caddy 1970). The high density contagions are actively sought by fishermen. Once located, they are systematically harvested until yield/tow becomes uneconomic. Sea scallop catch-per-unit-effort (CPUE) is reported usually in kg/crew-hour-meter (kg crhm^{-1}). For the offshore beds catch rates typically range from about 0.2 to 0.6 kg crhm^{-1} (Table 15.5). The 1990 catch rate series for Browns Bank is well above the norm although it is regularly exploited (200–2,000 metric tons of meats annually). They correspond to a fishery developed on the northern part of Browns Bank in areas not previously fished. Right from the start in 1989, the fishery has been managed with a quota and a meat count (Robert and Butler 1998). Good densities and good yields equate above average catch rates. As in *Patinopecten yessoensis* (Querellou 1975), postsettlement dispersal from within area(s) of primary settlement sometimes occurs through random swimming activity of juveniles (Caddy 1968; Morton 1980) resulting in their being further dispersed usually along tidal axes (Posgay 1981; Melvin et al. 1985) to form typically elongated or elliptical scallops beds (Posgay 1981; Robert et al. 1982; Melvin et al. 1985; Caddy 1989). Caddy (1989) has postulated the existence of intraspecific density regulation and is of the view that this may account for the low densities with size (age) observed in nature. Densities within a 117 km^2 scallop bed on Georges Bank in 1970, for example, were estimated to be between 2 and 4 scallops m^{-2} . Elsewhere, in the Northumberland Strait scallop densities have been variously reported to be between 4 and 6 scallops m^{-2} (Caddy 1968) and up to 4–7 scallops m^{-2} (Caddy 1970). Similarly, densities of between 2 and 4 scallops m^{-2} have been reported from a northern shallow-water population in Port au Port Bay (Naidu 1969). The high density contagions frequently are too small to be adequately addressed in random stratified sampling schemes

particularly when employed over large areas and pose undue problems for estimation of resource abundance. Notions of scallop distribution and densities in a scallop bed will likely be challenged by the recent availability of multibeam sonar backscatter bottom maps. Preliminary investigations on Browns Bank strongly correlate habitat types defined by sediment with scallop densities (Kostylev et al. 2003).

Although there is some overlapping of areas of settlement, sea scallop beds characteristically are dominated by one or few year-classes (Caddy 1968, 1970, 1971b, 1972). Not surprisingly, it is not uncommon to see dredge-sampled catch to comprise of similar-sized individuals (Fig. 15.3). This homogeneity in size composition is particularly striking in fringe areas where the fishery may sometimes rely almost entirely on a single age cohort.

15.6 GEAR AND BOATS

The sea bottom where scallops are found is highly variable, usually consisting of mud, sand, pebbles, rocks, and even boulders, but highest densities tend to be on bottoms where byssal attachment is likely, e.g., glacial till (Caddy 1989). Extremely rugged gear may be required depending on the type of sea bottom. Improvised rakes of unspecified configuration have been used from the early days with varying success. With the advent of motorised vessels, greater complexity in gear design and fishing techniques became possible. Majority of landings comes from vessels using scallop rakes (dredges or drags). Specially modified groundfish trawls are sometimes used (Dr. F.M. Serchuk, pers. comm.). For a summary of scallop gear used in various fisheries, including those commonly used for harvesting sea scallops, the reader should consult Stone and Hurley (1987). These include the Digby-type rake (Fig. 15.4), the Green sweep drag, Cayenne drag, Alberton drag, the Japanese (Keta-ami) dredge, and the Scottish spring-toothed drag. Because of their relatively small size the foregoing gear types are usually used in shallow waters nearshore. Inshore vessels sometimes use up to 9 Digby-type rakes individually shackled to a single tow bar. Each component of the gang of drags operates independently of one another. This allows the fleet of drags to conform closely to the bottom contours so typical of the eulittoral zone. Overall efficiency for the various inshore rakes is typically low. Efficiency of Digby drags for capturing sea scallops on rocky and smooth bottoms, for example, has been estimated to vary from about 5 to 12%, respectively (Dickie 1955). Higher efficiency on smooth grounds is attributed to improved gear performance through more consistent contact with the substrate. The offshore scallop rake (New Bedford scallop drag) is one of the sturdiest fishing gears used in the capture of sea scallops (Fig. 15.5). Widely used in the offshore scallop fishery in Canada and the United States, it has undergone little change since it was first introduced. Essentially, the drag consists of a heavy metal frame and a bag knit with steel rings 3 or 4 inches in diameter and variously inter-connected with links. Rubber chafing gear is sometimes used to extend the life of the rake, particularly when fishing hard bottom. Chafing gear can be of two types: shingles which are attached in rows to the belly of the rake to decrease wear on links and rings and rubber rollers which are fitted to the full length of the club stick. When fishing smooth bottom, a bag may last for as long as five

Figure 15.3. Typical haul of sea scallops from St. Pierre Bank showing single-cohort recruitment.

Figure 15.4. Gang of 4 Digby scallop rakes commonly used in the inshore sea scallop fishery.

Figure 15.5. New Bedford scallop rake used in deeper, offshore waters.

trips; but on rocky bottom, it may not last for even one trip. For a detailed description of the New Bedford scallop drag the reader is referred to Bourne (1964). The efficiency of the offshore rake is somewhat higher than for inshore drags and estimated to be 15.4% (Caddy 1971a). Progressively higher capture efficiencies were observed with increasing shell size with highest efficiency recorded for the larger, non-motile scallops (Caddy 1968). Swimming activity rather than selection by the drag appears to be responsible for the low drag efficiency for the capture of scallops smaller than 100 mm (Caddy 1968). Also, overall efficiency of the offshore dredge was higher over gravel on Georges Bank than on sand in the Gulf of St. Lawrence (Caddy 1968).

Factors known to affect the size selectivity of various types of gear commonly used in capturing sea scallops include inter-ring spacing (Medcof 1952; Caddy 1971a); ring size (Medcof 1952; Dickie 1955; Bourne 1960, 1962, 1965; Posgay 1958; Caddy 1971a; Serchuk and Smolowitz 1980; Smolowitz and Serchuk 1987); mesh size used in the rope back (Caddy 1968); rock chains (Bourne 1965; Smolowitz et al. 1985); tooth length, width and spacing (MacPhail 1954; Caddy 1973); chafing gear (Smolowitz and Serchuk 1987); substrate composition, and escape responses. Repeated towing over the same ground may also improve overall efficiency due to smoothing effects of the gear on the bottom (Caddy 1977). Most of the selection, particularly for larger sea scallops, is passive.

The majority of selection studies for the sea scallop have attempted to increase escapement of small scallops by increasing the internal diameter of the rings. While selective size retention favouring larger scallops has generally been a major concern, its resolution has been somewhat problematical because of the accumulation of trash, including disarticulated shells and progressive masking with tow time of ring size and ring numbers, resulting in the impairment of selectivity particularly during saturation tows. It is apparent, however, that much of the selection takes place through the inter-ring spaces through the belly than through the back.

Overall efficiency of capture is determined by gear configuration, behaviour (example, propensity to being bysally attached, swimming ability, and endurance), substrate composition and consistency, and speed of tow. Sea scallops are among the most efficient swimmers in the Family (Pectinidae) (Morton 1980). The low capture rate for small sea scallops is no doubt related to their ability to elude capture gear by swimming (Caddy 1968).

Two size-classes of vessels are usually recognised. Typically, inshore components are under 19.8 m (65 ft, LOA) while the offshore or deep sea fleet consists of larger vessels, sometimes approaching 46 m (150 ft, LOA) (Fig. 15.6). Vessels not only employ rugged gear but also must be quite powerful and seaworthy. Once built of wood (Royce 1946; Posgay 1957b), the tendency now is towards steel hulls. The smaller, wooden boats average about 40–60 gross tons and are powered by 200–300 hp diesel engines. They have extensive sheathing and protection against chafing by the warps and rakes. While some of them continue to make excursions offshore, particularly during the summer, they are normally restricted to operations nearshore. Their normal crew complement is between 11 and 13 men, including skipper, mate, cook, and engineer. The larger steel vessels averaging between 280 and 360 gross tons are powered by 650–1,200 hp diesel engines. Offshore vessels operate 24 hours a day and are capable of fishing year-round. Typically they carry up to 24 men for a 12-day excursion. Modern vessels are equipped with navigational gear, including DGPS (Differential Global Positioning System), satellite receiver-computers, with plotters, radar, depth sounders, automatic pilots, single and side-band, and VHF radios. Since 1998 the deep sea fleet is equipped with 'black boxes' (satellite-based monitoring systems) for tracking vessel activity and secure messaging.

15.7 EXPLOITATION AND RESOURCE MANAGEMENT

The Atlantic sea scallop fishery is of major importance to both the United States and Canada. In the United States, responsibility for the control and administration of all aspects of fishery resources is shared between public Fishery Management Councils (Regional), the Federal Department of Commerce and State Governments; in Canada, it is with the Minister, Federal Department of Fisheries and Oceans. The status of scallop resources is assessed periodically, particularly for the more important stocks. An extensive literature exists on the state of exploited scallop aggregations throughout its range (see other chapters in this volume). Exploitation of most important stocks like Georges Bank is evaluated on a regular basis in the United States or annually in Canada. On the American side of Georges Bank research vessel surveys play an important role to

provide estimates of fishing mortality and stock biomass. There are concerns that the modified Delury model used so far underestimated stock size; a proposed two-stage dynamic model in a Bayesian framework might help (NEFSC 1999). There are difficulties with the collection of commercial fishery data. The stock evaluation is further complicated by the existence of closed areas; for example, fishing mortality rates are estimated for the stock as a whole but they actually apply to the portion of the stock from the open areas only. In Canada, stock assessment and short-term projections are based on biomass estimates from research vessel surveys, relative age frequencies and temporal changes in the commercial catch and catch per unit of effort. Sequential population analysis (SPA) has been carried out on scallop populations on Georges Bank (e.g., Mohn et al. 1989, Robert et al. 2000). General production models are not easily reconciled with the severe dynamism exhibited by the species. A Collie-Sissenwine production model (Collie-Sissenwine 1983) was applied to Georges Bank data in the last assessment with mixed results. But the two types of models revealed the same trends for fishing mortality rates and biomass estimates.

Figure 15.6. Typical offshore scallop vessel.

Contagious distribution of young scallops poses special problems in designing research surveys, as do sometimes the smallness of the aggregations themselves. The U.S. survey on Georges Bank, for example, uses a stratified-random design with scallop-sampling strata based on water depth and latitude (Serchuk and Wigley 1986; Lai and Hendrickson 1997). To reflect the impacts of closed areas implemented in the Georges Bank region in 1995 and in the mid-Atlantic region in 1998 sampling stations were reallocated among open and closed strata and the total number of sampling stations increased starting in 1997. The Canadian survey design uses a stratified-random scheme with sampling strata based on past commercial catch-per-unit-effort contours derived prior to each survey (Caddy and Chandler 1979; Jamieson and Chandler 1980; Robert and Jamieson 1986). The survey design was refined in 1997 to increase the precision of the estimated number of scallops either adults (Smith and Robert 1998) or juveniles. Juvenile scallops were poorly represented by the commercial data stratification due to small size; an adaptive strategy is reducing the variance by 30% (Robert et al. 2000). Whereas the former attempts to estimate total biomass, the latter methodology recognises the fishable area to be limited and, consequently, is more concerned with the fishable biomass (Mohn et al. 1985). Resource managers use the scientific advice to manage the fishery in their respective jurisdictions frequently preferring a holistic approach by taking into account prevailing socio-economic conditions.

Historically, regulations in the American offshore scallop fishery had been imposed by industry; they included crew size, trip restrictions such as time spent at sea and time between trips, etc. With the advent of the 200-mile Fisheries Conservation Zone, the New England and mid-Atlantic Fisheries Management Councils developed sea scallop Fisheries Management Plan (FMP) to regulate the fishery in 1982. Initially the FMP had a 40 meats per pound size limit with a minimum shell height of 3 inches. A year later, the Regional Director invoked the temporary adjustment provision in the FMP by setting a 35 meats per pound and a 3 3/8 inch minimum shell height. The minimum shell height was subsequently raised to 3 1/2 inches in 1988. These measures met with resistance from industry and did not entirely fulfil the intended purpose of improving yield per recruit. The single set of measures applied to the whole area where sea scallops occur and did not allow for local differences in biological growth-rates (for example). Also, the size limit stating the number of meats in a pound allows mixing very small scallops with a few large ones as long as the limit is met. The FMP Amendment #4 (NEFMC 1993) introduced in 1994 shifted scallop fishery management from meat count regulation to effort control for the entire American conservation zone. New measures included a day-at-sea reduction schedule, an increase in minimum ring size, a decrease in crew members, and several restrictions on dredge gears. The days-at-sea for full time participants declined from 204 in 1994 to 120 in 2000. The minimum ring size went from 3 inches to 3 1/2 in 1996. Maximum crew size went from 9 to 7 shortly thereafter. Dredge gears could not have chafing gear; double links, triple links in belly allowed only; no less than 5 inches mesh twine top. In December 1994, 3 groundfish closed areas were implemented on the U.S. side of Georges Bank. Scallop fishing was also prohibited in the closed areas to reduce bycatch and protect groundfish habitat. Subsequently, scallop fishing effort moved from Georges Bank to the mid-Atlantic region increasing exploitation and decreasing stock

abundance in the latter region. In March 1998, 2 areas of the mid-Atlantic region were closed to scallop fishing for 3 years to increase yield per recruit and spawning biomass. Substantial abundance of young scallops had been observed in the 2 areas (NEFSC 1999). Amendment #7 to the FMP implemented a definition for overfishing in 1998 via biological reference points ($F_{\max}$, $B_{\max}$ as a proxy to B_{MSY}); this was required by the Sustainable Fishery Act. Over the last 2 years the FMP has been modified to allow for limited exploitation in portions of 2 of the Georges Bank closed areas under strict rules (possession limits, gear restrictions and stowage while transiting, days-at-sea accrual, in-season catch adjustments, etc.). For commentaries on this very complex fishing plan, see Kirkley and DuPaul (1998).

Scallop dredges used in the sea scallop fishery are characterised by relatively poor species-specific and size selectivity. Bycatch issues revolve around the capture of undersized scallops and groundfish that are either retained or discarded and the ancillary damage to bycatch animals in the gear and on deck. Gear modifications like increasing dredge ring size have reduced the collection of small scallops but damage still occur through gear handling on deck. Mortality rates on groundfish bycatch are perceived to be high and wasteful if retention is not allowed or desirable (DuPaul et al. 1996). Modest success in groundfish escapement has been reported by changing the mesh in the dredge twine top. Changes in harvesting practices like taking steps to discard unwanted animals overboard immediately at haul-back could make a big difference with little effort.

Regulations affecting the Canadian offshore scallop fishery were developed primarily for Georges Bank (Caddy and Sreedharan 1971). Then, as now, Georges Bank accounted for most of the landings. It is also the area with the best growth-rate and good recruitment patterns. As other offshore aggregations became exploited, some regulations such as the size limit were modified to reflect different biological environments. Mandatory logs for vessels 19.8 m or more in overall length were introduced in Canada in 1973 (Sinclair et al. 1985). In 1976, the Canadian offshore fishery became designated as one of limited entry to control total effort expended. Regulations also specified trip limits (13,700 kg) and trip duration (not exceeding 12 consecutive 24-hr periods) in 1977. In many areas, sea scallop fishing regulations are primarily aimed at optimising the age of first capture (Posgay 1958). This is achieved through the imposition of a size limit that seeks to maximise yield per recruit from the population. Most important in terms of addressing total fishery yield and maximum yield/recruit is the meat count, which specifies the number of scallop meats allowed per unit weight. As the average scallop size increases, the meat count declines. It is an average count with attendant difficulties. The Canadian offshore fishery has been under meat count regulation since 1973. When first introduced the count was 60 meats per pound. From a yield point of view, this meat count was set too high to be effective but it introduced the regulation measure. The meat count was lowered to 50 meats per pound in 1974, then to 45 in 1975 and 40 in 1976. The next decrease, to 35 meats per pound or 39 meats per 500 grams, waited until 1983.

When both Canada and the United States declared a 200-mile fishing zone extended jurisdiction in 1977, most of Georges Bank became a disputed zone claimed by both countries. Competitive fishing by both the Canadian and American scallop fleets continued in the disputed zone and grew more intensive until 1984, when the International

Court of Justice established an international boundary in the Gulf of Maine. The northeast section of Georges Bank was awarded to Canada. As a result of the no-rules fishery leading up to the Court decision, the 1984 Canadian scallop landings from Georges Bank were less than 2,000 tonnes of meats or 16,000 tonnes round weight, the lowest catch on record.

After the dispute affecting fisheries jurisdiction on Georges Bank had been settled, the Canadian scallop industry focused on stock rehabilitation through better harvesting of the resource. There were 3 goals: optimise the yield, reduce the fishing effort, and inject a degree of stability in landings. Catch quotas (TAC's) were imposed on the offshore scallop fleet as enterprise allocations (EA's). Each of the offshore companies holding fishing licences receives a percentage share of the annual TAC; a company may utilise one or more vessels to catch its share. The percentage shares were negotiated between licence holders in 1986; they were based on historical fishing performance on Georges Bank and the number of licences held by each company. At first, only Georges Bank was managed under EA's; gradually all offshore fishing areas were integrated under TAC's, the last one in 1994. Since 1986, annual removals have generally stabilised (Fig. 15.7). There were 77 active licence holders in 1984. Only one third the initial number of licence holders are actively involved in the fishery today. But the fishing power has not necessarily been reduced by the same ratio. A quasi-property management regime appears to succeed where other regimes such as input control in the inshore fishery have been far from successful (Brander and Burke 1995). The meat count for Georges Bank was lowered to 33 meats per 500 grams in 1986 to direct exploitation toward slightly larger scallops. The meat count for the western areas of the Scotian Shelf is set at 40 per 500 grams and 45 for the eastern Scotian Shelf.

Compliance with the meat count is readily achieved through blending large meats with smaller ones, the latter frequently being predominant in the landed catch (Naidu 1984). This strategy legitimises the harvesting of considerable numbers of small scallops. As the regulation was intended primarily for the protection of young scallops and delaying capture of those only recently recruited to maximise yield per recruit, the meat count in its present form has not had the full intended regulatory effect to total management of the resource. This has been demonstrated for St. Pierre Bank where the proportion of young scallops in the catch has been shown to sometimes exceed 65% (Naidu 1984). An attempt to partially redress the effects of blending in the meat count measure was the voluntary introduction of 50-count tolerance in the catch. In 1995, a voluntary monitoring program to discourage the presence of small meats in the catch (50+ meats per 500 grams) was implemented. A low tolerance level (10% by number of meats 10 grams or less) added more restriction to the regulatory 33 meats per 500 grams. The tolerance measure on small meats had its greatest effects on the Georges Bank fishery because of its recruitment driven nature. Trends in exploitation rates on age 3 scallops, the youngest age recruiting to the gear, show exploitation rates over 40% in 1981 when the meat count regulation had been relaxed and a strong year class was recruiting to the fishery (Robert et al. 2000) (Fig. 15.8). The meat count reduction to 33 meats per 500 grams in 1986, shifted age at first capture to a slightly older scallop and exploitation on age 3 became minimal at 5%. It has been reduced to almost nil with the monitoring of small meats in the catch starting in

Figure 15.7. Profile of catches and TAC (since 1986) in tonnes of meats from the offshore scallop fleet for the Canadian side of Georges Bank, 1972–1999.

Figure 15.8. Exploitation rates on age 3 and the directed age group (ages 4–7) for Georges Bank offshore scallops since 1981.

1995. The aggregation of scallops into beds allows the fishery to direct its activities toward a sedentary target of specific size. The exploitation rate on the age group most important to the fishery (ages 4–7) has experienced less variability since the implementation of EA's. It varied little from 40% between 1988 and 1994. Recently, exploitation rates have generally been lower, in the 20% range. An annual time series of average meat count and percentage of meats 10 grams or less in the catch presents the same key elements (Fig. 15.9). While the meat weight distribution in the catch is a reflection of 3 variables: the meat size distribution in the stock, the quota, and meat count restrictions, the count and its derivatives may improve yield provided that it is low enough to be effective.

The decision-making process related to the offshore scallop management regime operates on a consultative basis. Advice to the Department of Fisheries and Oceans (DFO), Government of Canada (the fishery manager) is through the Offshore Scallop Advisory Committee (OSAC). The Committee provides input and advice to DFO on the conservation, protection, and management of the offshore scallop resource. It serves as the pre-eminent consultative forum for the development of the annual offshore scallop fishing plan (Anonymous 1999). There is no hard and fast rule to TAC setting. Overfishing concerns are considered in the light of rational harvesting and biological advice. The Committee's other terms of reference deal with regulatory measures, the administration of the EA programmes, and the introduction of new fishing technologies.

Catch size distribution

Figure 15.9. Distribution of scallop meat sizes in the commercial catch from Georges Bank, 1981 to 1999. The meat count is the number of scallop meats per 500 grams. The percentage of meats weighing 10 grams or less from commercial catch samples is also shown.

Bycatch issues have been the focus of discussions at OSAC. Since 1996, all incidental catches of all groundfish species, except monkfish, are returned to the water. Monkfish have accounted for approximately 85% of the groundfish bycatch landed by offshore scallop vessels (Anonymous 1999). The scallop industry has been proactive in testing gear modifications to reduce bycatch of groundfish and undersized scallops (Anonymous 1995). The use of large square mesh in the twine top of the dredge led to a decrease in the capture of groundfish like cod and haddock but flatfish like flounders are more difficult to deal with. Additional research is needed not only in gear modifications but also in harvesting practices to curtail bycatch mortalities.

Regional or District closures are dictated by the perceived incompatibility of recreational pursuits with commercial fishing activity and or the alleged interaction between scallop dragging and its effect on lobster grounds and lobster trapability (Jamieson and Campbell 1985). Lobsters are known to avoid moving drag rakes (Scarratt 1972). In one study (Pringle and Jones 1971), only one lobster was captured during approximately 30 hrs of fishing with a rock drag. With some clear exceptions (e.g., the Green sweep drag), lobster bycatch appears to be negligible. Neither is there evidence to suggest that scallop drags modify permanently the preferred habitat of lobsters. Physical gear conflicts with passive lobster gear, however, is likely and, presumably, is the rationale behind the institution of selective closures where the two activities must coexist. Management measures sometimes are developed and applied on a regional basis. In the Bay of Fundy, for example, closures are instituted that maintain some of the more productive grounds close to shore for exploitation during the winter months. The offshore drag and the Green Sweep scallop drag are banned. Regulations controlling minimum ring size (82 mm, inside diameter) and effective total width (5.5 m or 16.4 ft) of fishing gear are also in effect.

Provisions for temporary closure of areas, even if seldom enforced, is nearly always included in the Fishing Regulations. This facilitates the issuance of variation orders as and when the need arises. Management measures in the U.S., for example, allow for temporary adjustment of the meat count and shell height standards. The Canadian roe-on fishery for adductor muscles with gonads attached recognises the sporadic occurrence of paralytic shellfish poisoning (PSP) and domoic acid in scallops. While the toxins have little or no visible effect on the shellfish, they have proven to be poisonous to humans. Regulatory agencies, both in Canada and the United States, have developed necessary safeguards and protocol for the harvesting and marketing of roe-on scallops. All product is subject to detention, sampling, analyses, and certification prior to marketing. Toxicity levels are rigorously monitored throughout the fishing season. Should the results of the analyses exceed established standards (in Canada, PSP under $80 \mu\text{g } 100 \text{ g}^{-1}$; domoic acid under $20 \mu\text{g } \text{g}^{-1}$), the product is subject to forfeiture and the source area and all adjacent grounds are immediately closed. Three consecutive acceptable levels over a 14-day period are required before the suspect area may be reopened. As only scallop roes become toxic, the problem is restricted to areas where meats are kept with the roe attached. The adductor muscle does not accumulate the toxin. The roe-on fishery is limited to Georges Bank, Western and Sable Banks, and the bulk of landings occurs between May and June when the roe is well developed. The rather limited Canadian roe-on fishery commenced in 1987 and has continued off and on to the present. Between 10

and 100 metric tons of roe are harvested annually, primarily for the European market. As only a small percentage of sea scallops are visibly hermaphroditic (Naidu 1970; Worms and Davidson 1986a), it has been necessary to duplicate the dioecious condition (as in *Pecten maximus*) by mixing approximately the same numbers of testes and ovaries in order to commercialise the product.

Inshore stocks in Canada are generally not regulated by a minimum meat count or minimum shell size. When in force it varies with location and, for a given area, it may even change seasonally. In the Northumberland Strait, for example, it remains at 52/500 g throughout the year. In the Bay of Fundy, the count used to vary from 55/500 g (October to April) to 72/500 g (May-September); currently it is 45 meats per 500 grams throughout the Bay. Elsewhere, including St. Pierre Bank the meat count remains at 33/500 g (30/lb) year round. Maine is the only State in the United States that imposes a season (November 1 to April 14) in its territorial waters (Mullen and Moring 1986). In the United States, removals are subject to both State and Federal Regulations. All removals are subject to the meat count, currently set at 30/lb (or 3 1/2 in or 89 mm shellstock). Although the minimum shell size stipulated is smaller than the average size corresponding to the blended count of 30/lb, it represents the absolute minimum size required to produce a nonviolative legal count. Consequently, enterprises in the United States sometimes find it advantageous to land scallops in the shell. A recently introduced regulation now requires scallop fishermen to unload their catches during specified daylight hours.

In some areas scallops may be in close proximity to industrial centers and consequently exposed to contaminants. Heavy metal (Pb, Zn, and Cu) levels in scallop tissues may become elevated in scallops found close to areas where storage and or shipboard ore loading had taken place over extended periods (Barrie 1984). Ray et al. (1984) have shown cadmium burdens in scallops from some areas offshore (example, Browns and Georges Bank) to be generally higher than from other areas such as Chaleur Bay, New Brunswick (Canada). Later, Uthe and Chou (1987) found that the higher levels were not due to contamination from anthropogenic or natural sources, but rather indicate that scallops were feeding on a nutritionally marginal diet containing relatively large amounts of cadmium.

Recreational fishing activity include the use of SCUBA (self-contained underwater breathing apparatus) and the use of rakes, tongs and dip-netting. In Canada, an individual fishing for scallops under a recreational fishing license is allowed no more than 100 scallops in any one day. In the United States, a non-commercial license permits a daily bag limit of two bushels of shellstock, or 4 quarts of meat. Also, it is unlawful to fish for or take scallops during night-time within Maine's territorial waters. Recreational activity is restricted to shallow water throughout the Gulf of Maine, Nova Scotia, north shore along Quebec, and around Newfoundland. While relatively insignificant in terms of volume removed, its per-unit-weight contribution to the economy is sometimes quite considerable.

Because of the high unit value, the species continues to be fully exploited. Frequently, they are harvested before reaching the size corresponding to maximum yield per recruit. While increasing age at first capture and decreasing fishing mortality are widely recognised as desirable management objectives in increasing the long-term yield

from the resource as demonstrated by the Canadian Georges Bank fishery, yield-per-recruit and stock projections show that the species is in some cases overexploited, sometimes at a level higher than $F_{\max}$.

15.8 OUTLOOK

The extreme dynamism of this species precludes long-term catch projections. Production will depend on recruitment patterns and the nature of management regime selected particularly for the offshore fishing areas. Fishery performance on Georges Bank will continue to influence patterns of exploitation elsewhere on the Atlantic seaboard. Over the short term, exploitation scenarios of a very different nature could take place. For example, accumulated biomass in the closed areas of Georges Bank (U.S. side) could provide levels of catches in relation with the opening of areas. Exploitation strategies could help along to optimise the catch. It would also relieve some of the fishing pressure exerted on the mid-Atlantic sea scallop beds. In Canada, sound management practices in the offshore and good incoming recruitment on Georges Bank should maintain landings at average historical levels or better. Production in the Bay of Fundy reached 38,000 metric tons in 1989, the highest in its 100-year history. Since then, lack of important recruitment and very high levels of effort have kept the fishery from performing. A pulse of good recruitment has been observed recently but the success of the fishery hinges in improving the management of the resource. The Northumberland Strait and other areas of the Gulf of St. Lawrence will continue to have only a marginal input to the overall Canadian landings. Inshore, because of wide fluctuations in recruitment, sustainable yields will continue to be highly variable; pulse fishing related to stock abundance and economic factors will dictate the pattern of exploitation.

In Canadian waters, two recent introductions will change the course of the offshore scallop fishery, satellite-based vessel monitoring and 3-D bottom imaging. Monitoring of vessel positions by satellite tracking has been introduced in early 1998. The monitoring provides improved knowledge of effort distribution both in time and space. While conventional logbooks give an estimated fishing location on a daily basis, satellite polling allows for multiple, at random if so wished, queries on vessel's location during the course of the day on a real time basis. Objectivity no doubt is, the second advantage of the monitoring system. Contrary to positions recorded in logbooks by fishers, there is no interpretation involved with the satellite-based monitoring system. Accuracy in location of fishing activities, especially with a sedentary target like sea scallop, is much improved with Global Positioning System. Applied to the offshore scallop fleet, the technology has allowed micro-management of fishing areas to become a reality. Most of the scallop grounds are prime habitats for the sea scallop and have traditionally been fished to this day. At times, scallop beds form in marginal habitats and although shell growth is similar to the prime areas, meats are small and slow growing. Scallop abundance in marginal habitats could be high but the size of the meat would make it difficult to fish at legal count and these grounds would be more or less ignored. If and when warranted, a management area is divided into the traditional area where the mainstay of the fishery continues to be managed as usual and a marginal area with a separate management regime where the meat

count may be set higher. The fishery management by EA's also requires a quota for such a marginal area. The lack of historical fishery data or survey information precludes the use of most stock assessment tools. Rolling TAC's have been used in a few offshore areas over the last 3 years; the success of the measure rests mostly with the full co-operation of the scallop fleet. A rolling TAC has 2 key elements: a small quota (100 or 200 tonnes meats) to be fished over a short period, say 6 weeks at a set meat count. At the end of the first 6 weeks period, catch rates and meat counts are evaluated. Quota increments are repeated provided catch rates do not drop significantly and meat counts are met without difficulties (Robert and Butler 1997). Fishing areas can now undergo effective closures without the expense of enforcement patrols. Closures may be invoked to protect broodstock, nursery areas, sensitive habitats, etc. A seed closure was implemented on Browns Bank in late 1997 after the annual stock survey found low density levels of juvenile scallops throughout the Bank except for a patch of very high densities on the northern edge. The closure was lifted only after the year class of juveniles had reached commercial size.

The application of 3-D bottom imaging (Fig. 15.10) is changing fishing strategies into harvesting practices (Manson and Todd 2000). Using the latest technology in multibeam sonar, maps detailing seabed habitat, topography, and geology have been produced for the main offshore scallop fishing areas. The mapping information offers powerful new tools to improve the management of both the fishery and the habitat. Mapping scallop grounds has improved catch rates, 2.5X in one area; it reduces bycatch and bottom disturbance; it improves vessel operating efficiency with reduced gear costs and lowered fuel consumption. Less fishing effort means reduced incidental fishing mortality on scallops and other fauna. Maps of scallop habitat laid over survey and commercial catch data allow the harvesting of commercial size scallops while avoiding concentrations of juveniles. The ecosystem may become better protected. Once sensitive habitats are identified and mapped, managers could introduce protective measures more easily.

Interest has been manifested in conducting exploration activities for oil and gas on Georges Bank. In the early 1980's, exploration wells were drilled on the U.S. side of the Bank. In response to concerns about potential risks to the Georges Bank ecosystem from petroleum exploration a first series of moratoria on oil and gas activities ensued on both the American and Canadian sides of the Bank. A condition of the Canadian moratorium was a review, by 1999, of the environmental and socio-economic impacts of exploration and drilling activities. Through the Georges Bank Review Panel the ecological status of Georges Bank was reviewed for potential impacts of petroleum exploration activities (Boudreau 1998). In 1998, the U.S. President extended the moratorium over U.S. waters to the year 2012. Although actual impacts of exploratory drilling would be time and area-specific, there were uncertainties associated with various other aspects of the review. In the end, the Panel recommended the moratorium to be continued. It also, has been extended until the year 2012.

Figure 15.10. Multibeam bathymetric map showing rough terrain, dome-shaped sand dunes called barchans, and a gravel bed on the left near the top of the picture.

Chapter 16

Sea Scallop Aquaculture in the Northwest Atlantic

G. Jay Parsons and Shawn M. C. Robinson

16.1 INTRODUCTION

Scallop culture in the Northwest Atlantic primarily involves the sea or giant scallop *Placopecten magellanicus* (Gmelin, 1791) whose culture is presently the basis of a slowly expanding and evolving industry. Within the last two decades, the aquaculture potential of the sea scallop has been widely reported (Naidu 1978; Naidu and Cahill 1986; Young-Lai and Aiken 1986; Gaudet 1989, Couturier 1988; Tremblay 1988; Wildish et al. 1988; Dadswell 1989; Dadswell and Parsons 1989; Couturier 1990; Robinson 1993; Dabinett and Couturier 1994; Couturier et al. 1995; Cliche et al. 1997; Neima 1997; Dadswell 2001; Grecian et al. 2003). The attractive characteristics for the sea scallop can include good spat supply, fast growth, large meat size, high fecundity, reliance on natural sources for food supply, high market value, available markets and consumer acceptance. The biological feasibility of producing a market sized scallop within two to three years has been demonstrated (Dadswell and Parsons 1991) but early reports of its economical feasibility were not as favourable (Frishman et al. 1980; Gilbert and Cantin 1987; Wildish et al. 1988), mainly due to projected slow growth and high costs of equipment and labour. New technology and research on optimising the methodology and handling of scallops has helped to change the economic outlook to that of a viable venture (Dadswell and Parsons 1992a; Ford 1997; Penney and Mills 2000). Innovative culture-based methods (to Atlantic Canada) have also been suggested to increase the production of existing scallop beds (Robinson 1993), which are now being implemented.

Scallop culturing technology and methodology are derived from the Japanese experience, which first started on a large scale in the 1950's (Imai 1977; Ventilla 1982; Aoyama 1989). The basic procedure involves four steps: 1) spat or seed procurement, 2) intermediate culture, 3) final grow-out, and 4) harvesting and marketing (for general scallop culturing manuals see Mottet 1979; Bourne et al. 1989; Neima 1997). Spat procurement relies on either hatchery-produced spat or obtaining wild spat using artificial collectors, which usually consists of "onion" bags filled with monofilament gillnetting or other materials. Intermediate culture of juveniles consists of growing scallops in pyramidal or conical shaped "pearl" nets until they are large enough for the next stage. For final grow-out to market size there are several different types of technology including pearl nets, lantern nets (a multi-tiered accordion style net), trays, large cages, ear hanging (where a hole is drilled in the "ear" or auricle of the scallop and they are hung on suspended ropes) or bottom culture (enhancement) (where scallops are seeded directly on

the bottom). The traditional product is the meat, but higher value roe-on meat and whole scallop ("princess") markets do exist.

The bay scallop *Argopecten irradians* is an introduced species to Atlantic Canada and interest in culturing this species in this region has declined of late. For a description of earlier efforts, see Couturier (1990) and Couturier et al. (1995). The Iceland scallop *Chlamys islandica* also exists in parts of Atlantic Canada and there has been minor interest in culturing this species in Québec (lower north shore), but these efforts are not reported here (see Frechette et al. 2000; Frechette and Daigle 2002; Thomas et al. 2002).

16.2 HISTORY OF SEA SCALLOP CULTURE

The history of sea scallop culture can be traced to the early efforts of Newfoundland researchers in the 1970's. With the decline in the once lucrative fishery, especially in the Port au Port area, research was initiated to examine potential for restocking and enhancing the local populations (Naidu et al. 1989; Naidu 1991). These early efforts focussed primarily on spat collection techniques as a means of securing a large supply of juveniles (Naidu and Scaplen 1979). It was a similar decline in the fishery of the Magdellen Islands and lower north shore of Québec that stimulated interest among Québec researchers to investigate techniques of scallop enhancement (Fournier and Marsot 1987). Their initial work concentrated primarily on hatchery rearing techniques but has expanded to wild spat collection and grow-out (Cliche et al. 1994; Giguère et al. 1995; Cliche et al. 1997; Nadeau and Cliche 1997, 1998). In the 1980's, scallop aquaculture research in Passamaquoddy Bay, New Brunswick and Mahone Bay, Nova Scotia evolved from a research program originally established to examine sea scallop recruitment processes (Dadswell et al. 1987; Dadswell and Parsons 1991; Parsons 1994). The research in New Brunswick and Nova Scotia has encompassed spat collection, intermediate grow-out and several methods of final grow-out. A large-scale project in Newfoundland in the 1990's under the Canada/Newfoundland Agreement on Economic Renewal Aquaculture Component (ACERA) resulted in the establishment of commercial-scale hatchery production and intermediate and final grow-out and equipment trials (Dabinett et al. 1998; Parsons et al. 1998).

There have been also two additional, large-scale research programs established to examine many aspects of sea scallop culture. The first was a multi-university program called OPEN (Ocean Productivity and Enhancement Network) and the second was a provincial/federal government program in Québec called REPERE (REcherche sur le Pétoncle à des fins d'Élevage et de REpeuplement). From these initial modest beginnings twenty-five years ago, operations have been established in Newfoundland, Prince Edward Island, New Brunswick, Nova Scotia and Québec with mixed degrees of success. Currently, there are small to medium scale commercial operations in Nova Scotia and Québec and a large-scale enhancement enterprise in Québec. As well, sea scallop culture efforts using both suspended and bottom culture techniques have been examined in Maine and off Martha's Vineyard in Massachusetts (Goudey and Smolowitz 1996; Karney 1996; Karney et al. 1996; Langan et al. 1997; Parsons et al. 2002). For a comprehensive description of the history of scallop culture in eastern Canada, see Couturier et al. (1995).

16.3 HATCHERY SPAT PRODUCTION

Large-scale hatchery production offers several advantages to potential aquaculturists including genetic selection of a regular and plentiful supply of scallop seed at a relatively low price. Viable larval rearing, using hatchery technology, has been reported for many species of bivalves including scallops, clams and oysters (Loosanoff and Davis 1963; Gruffydd and Beaumont 1972) and several comprehensive hatchery manuals have been written (Dupuy 1977; Castagna and Kraeuter 1981; Bourne et al. 1989; Neima 1997).

Early work on larval rearing of the sea scallop was conducted mainly to describe the development of the early life-history stages (Baird 1953, Bourne 1964) and Culliney (1974) was the first to ascribe the potential of artificial larval rearing for aquaculture purposes. The successful rearing of the sea scallop larvae through to settlement and metamorphosis had eluded researchers until relatively recently (Fournier and Marsot 1986; Cliche and Beaulieu 1989; Dabinett 1989; Mallet 1989; Karney 1996; Karney et al. 1996; Dabinett et al. 1998). These breakthroughs have stimulated much research on hatchery-related topics with the aim of producing an efficient and economical source of sea scallop spat (Manning 1985; Couturier 1986; Gillis and Dabinett 1989; Kean-Howie et al. 1991; Jackson 1992; Dabinett et al. 1998; Ryan 2000).

16.3.1 Broodstock Conditioning

The spawning season of most sea scallop populations occurs annually between July and October (Naidu 1970; Robinson et al. 1981; Barber et al. 1988; MacDonald and Thompson 1988; Parsons et al. 1992a; Grecian et al. 2001a). A semi-annual reproductive cycle has been described for *Placopecten magellanicus* in some areas (Dupaul et al. 1989; Dibacco 1991; Schmitzer et al. 1991, Dadswell and Parsons 1992a). The presence of two annual spatfalls has important implications for scallop aquaculture in enhanced spat collection and accelerated growth (Dadswell and Parsons 1992a). To assure a continuous supply of spat throughout the year, however, spawning has to be induced outside the normal spawning period. This can be accomplished by "conditioning" the adult scallops in the hatchery by manipulating their temperature and feeding regime in order to stimulate gonad production and ripeness (Neima 1997; Dabinett et al. 1998).

Successful attempts to condition sea scallops have been realised in the laboratory, in commercial hatcheries and by holding adults in suspended culture (Manning 1985; Couturier 1986; Neima 1997; Dabinett et al. 1998). Couturier and Aiken (1989) demonstrated a photoperiod effect on the reproductive cycle of the sea scallop, which appears to be key to conditioning scallops for successful spawnings throughout the year. Couturier and Newkirk (1991) found, however, that seasonal differences in spawning times can have an effect on larval vigour. Broodstock nutrition is also an important consideration; Napolitano et al. (1992) found that the allocation of lipids to eggs of wild scallops from well and poorly-fed populations were the same suggesting that the adults maintain the quality of eggs and vary the amount produced. Pernet et al. (2003a, b) and Pernet and Tremblay (2004) examined the link between lipid class variation and sea scallop gonad and reproductive state and larval development and performance.

16.3.2 Spawning Methods

The three methods most often used to induce spawning in bivalves include varying water temperature, increased water circulation and injection of serotonin. All three methods have been used singly or in combination to induce spawning successfully in sea scallops (Culliney 1974; Manning 1985; Couturier 1986; Fournier and Marsot 1986; Dabinett 1989; Marshal and Lee 1991; Dabinett et al. 1998).

Temperature cycling has been used to induce spawning in a number of bivalves (Loosanoff and Davis 1963). Generally, the technique involves either gradually or suddenly increasing or decreasing the temperature. Culliney (1974) was able to stimulate sea scallops to spawn by increasing temperatures by 3–5°C and Fournier and Marsot (1986) induced spawning by decreasing temperatures from 10°C to 4°C. A variation of this technique involves removing scallops from the water for 1 to 2 hours prior to re-immersion followed by thermal stimulation or serotonin injection (Gruffydd and Beaumont 1970; Young-Lai and Aiken 1986; Marshall and Lee 1991).

Dabinett et al. (1998) stated that scallops placed in shallow trays and subjected to increased water circulation (20 L min⁻¹) are usually induced to spawn within an hour.

Serotonin (a neurotransmitter) injection is a reliable method for inducing spawning in scallops. The procedure is to inject about 0.5 mL of 2 mM serotonin into the adductor muscle and spawning usually follows within a half hour (Matsutani and Nomura 1982; Gibbons and Castagna 1984; Couturier 1986). Other biochemicals that have been used for inducing spawning in other scallop species are potassium chloride (Beaumont and Hall 1999) and monoamines and prostaglandin (Martinez et al. 2000).

16.3.3 Egg and Larval Development

Eggs incubated at temperatures of 12 to 16°C reach the “D” larval (shelled) stage in 2 to 4 days. Growth rates of D larvae to day 28 larvae, which have been fed on a mixed algal diet, range from 2.0 to 6.4 $\mu\text{m d}^{-1}$ (Culliney 1974; Fournier and Marsot 1986; Couturier and Newkirk 1987; Fournier and Marsot 1987; Cliche and Beaulieu 1989; Mallet 1989). Larvae fed on mixed algal diets have better growth rates than those fed on unialgal diets (Mallet 1989; Dabinett et al. 1998; Ryan 2000). Marshall and Lee (1991) reported that larval sea scallops can use dissolved organic carbon (DOC), in the form of glycine, as a source of food. They further suggest that larvae are capable of competing with bacteria in the uptake of DOC. Larvae were also found to grow better when they were fed on algae in the log phase rather than the ‘stationary’ phase (Ryan et al. 1998; Ryan 2000). There was a positive correlation between growth of larvae and spat and sterol and methyl ketone content of the algae. In a similar study, larval scallop growth was found to be independent of the lipid content of the eggs, but was highly correlated with the genetic lines of heritability (Jones et al. 1996).

Larval survival rates are quite variable, yields from the egg to D larvae range from 30 to 76% and survival from egg to pediveliger (about day 28) range from 4.6 to 85.4% (Fournier and Marsot 1986; Couturier and Newkirk 1987; Fournier and Marsot 1987; Cliche and Beaulieu 1989; Dabinett 1989); Mallet (1989) reported an average daily

mortality of 3.2%. Couturier and Newkirk (1987) found a positive relationship between initial larval survival and adult gonad lipid levels, but egg size was found to be a poor indicator of larval survival (Couturier 1991).

16.3.4 Settlement and Metamorphosis

Larval settlement and metamorphosis represent a period of high mortality since it is a period of their life-history in which larvae undergo behavioural changes associated with their search for an appropriate substrate upon which to settle. Early attempts to induce settlement in sea scallops were either unsuccessful or larvae were reluctant to settle (Culliney 1974). If the proper cue or stimulus is not received, settlement can be delayed and high mortalities may result. With improved handling and rearing techniques some success in settling sea scallop spat have been realised at several hatcheries in Québec, Newfoundland and Nova Scotia over the last fifteen years (Fournier and Marsot 1986, 1987; Cliche and Beaulieu 1989; Dabinett 1989; Mallet 1989; Dabinett et al. 1998).

Sea scallop settlement typically occurs about 35 to 45 days after fertilisation at a size of about 250 μm (Culliney 1974; Fournier and Marsot 1986; Cliche and Beaulieu 1989). Fournier and Marsot (1987) and Cliche and Beaulieu (1989) reported survival rates of 0.5 to 10.9% from egg to postlarvae. Mallet (1989) found a percent metamorphosis of 2 to 5% and Dabinett (1989) reported 0.75 to 22.2% survival from the egg stage to 3 mm spat.

A variety of cultch (artificial substrate) materials have been used as settlement surfaces for the sea scallop (Tremblay 1988). Culliney (1974) found scallops to settle predominantly on the underside of small pebbles and fragments of glass and shell. Fournier and Marsot (1986) and Dabinett (1989) reported scallops settling onto Nitex™, scallop shells, and fibreglass tanks and panels. The use of chemicals, such as potassium chloride, L-Dopamine, epinephrine, GABA, etc., to induce settlement in sea scallops have been ineffective (Tremblay 1988). However, chitin from several sources (hydroids, crabs, shrimp, lobster) was found to be very effective at increasing larval settlement in both laboratory and field experiments (Harvey et al. 1997). Bacterial films have also been found to increase the larval scallop settlement rates (Parsons et al. 1993a; Pearce and Bourget 1996).

16.3.5 Spat Husbandry

Recent work has focused on the dietary requirements and feeding regimes of raising post-metamorphic spat in the nursery phase. Metamorphosis results in structural changes including the loss of the velum, which is used in larval feeding, and the development of a filter-feeding mechanism involving the new gills and cilia. The ingestion rate of the alga *Isochrysis galbana* by juvenile scallops was described by the relationship $IR = 1.5 \times 10^4 W \times 1.22$ where IR = ingestion rate (cells min^{-1}) and W = body weight (g) (Strickland and Dabinett 1993). However, Lesser et al. (1991) demonstrated that juvenile scallops feed selectively. Juveniles fed an unialgal diet selected particles based on size, whereas for those fed multialgal diets, selection did not appear to be based on size but rather on other characteristics of the algae or pre-ingestive sorting. A mixed algal diet, of

3 species, resulted in better growth than an unialgal or paired algal diet for 2 mm spat (Gillis and Dabinett 1989). Similar findings were reported by Parrish et al. (1999) and Milke et al. (2004) who found that mixed species diets worked better for growing juveniles and that omega 3 and omega 6 fatty acids were essential to providing an optimal diet. Mallet (1989) found analogous results for larvae (see 16.3.3). Hollett and Dabinett (1989) have found that a ration of $45 \text{ cells} \cdot \mu\text{L}^{-1}$ of a multialgal diet provided the best growth and highest spat growth efficiencies. Their experimental range of algal densities was 12 to $87 \text{ cells} \cdot \mu\text{L}^{-1}$.

Several recent studies have examined the physical conditions under which juveniles should be grown. Frenette and Parsons (2001) and Frenette (2004) showed that lethal temperatures were above 18°C and lethal salinities below 25‰. The highest filtering rates for juveniles were found at 13°C and 32‰ (Frenette et al. 2002; Frenette 2004). Unionised ammonia levels in the water were found to inhibit feeding of juvenile scallops at levels at $0.54 \text{ mg} \cdot \text{L}^{-1}$ and above (Dabinett et al. 1998; Grecian et al. 2001b). There was some evidence of size-related tolerances of ammonia as well as temperature-dependent sensitivity (Abraham et al. 1996).

Kean-Howie et al. (1989, 1991) studied the nutritional physiology of juvenile sea scallops and successfully developed a microparticulate food capsule upon which juveniles will feed. These studies have provided the basis for a more complete understanding of the specific dietary requirements of scallops, which have enabled researchers to manipulate the different dietary components of the microparticles. Coutteau et al. (1996) have used lipid emulsions as feed additives to increase the levels of n-3 highly unsaturated fatty acids in *Placopecten* and resulting in 20% more lipid being incorporated into juvenile sea scallops compared to the algal-fed controls.

16.4 WILD SPAT COLLECTION

16.4.1 Spat Collection Techniques

An alternative to producing spat in a hatchery is collecting wild spat using artificial substrates consisting of “onion” bags containing monofilament gillnetting. This technology or variations thereof, which are based on Japanese designs (Ventilla 1982; Ito 1990), has been successfully employed for many scallop species, including the sea scallop, *Placopecten magellanicus* (Buestel et al. 1979; Brand et al. 1980; Naidu et al. 1981; Grecian et al. 2001a). Spat collectors are suspended in the water column in an area that has a local population of sea scallops. The bags are generally deployed just after the scallops have spawned, which generally occurs from mid-summer to autumn (Naidu 1970; Robinson et al. 1981; MacDonald and Thompson 1988; Parsons et al. 1992a). Sea scallop larvae remain planktonic for about a month (Culliney 1974), after which they develop an affinity to settle on filamentous substrates (Larsen and Lee 1978) such as the monofilament gillnetting within the collectors.

Several factors can contribute to successful spat collection. Often, surveys for scallop larvae are conducted during the initial stages of spat collection programs to help choose potential spat collection areas (Parsons 1994; Giguère et al. 1995; Dadswell 2001).

Several studies have been conducted to determine the efficacy of different artificial settlement substrates (Naidu 1979; Parsons et al. 1996; Niles and Davidson 2002). Naidu (1979) found no differences in settlement of sea scallops on variously coloured substrates, but Naidu et al. (1981) did find that monofilament gillnetting was better than polyethylene sheets in obtaining sea scallop spat. They also determined that 540 g of monofilament gillnetting per "onion" bag (42 x 75 cm) was the optimum amount of material for this type of collector. It would appear that medium densities of medium diameter monofilament work better than very dense concentrations likely because of the water-flow characteristics created within the bag (Miron et al. 1995; Pouliot et al. 1995). Niles and Davidson (2002) found that black fuzzy rope was as successful as Netron for collecting spat. They also noticed that there were differences in collection efficiencies of ropes with different colours and suggested more work should be done on this aspect. Settlement intensity also varies with depth within the water column. Studies have shown settlement to be minimal near the surface and near the bottom and to be highest near the mid-depths (Naidu and Scaplen 1979; Dadswell et al. 1987; Bonardelli 1988).

16.4.2 Settlement Intensity

In Atlantic Canada, spat settlement studies have shown settlement to vary temporally and spatially, both on a local and regional level. From 1977 to 1987, spat studies at Port au Port, Newfoundland (NL) reported mean settlement to range from 5 to 600 spat per bag (Naidu and Cahill 1986; Naidu et al. 1989; Naidu 1991). Since 1988, with improved techniques and a better understanding of the vagaries of the bay, spat collection has been consistently greater than 3,000 spat per bag (Lanteigne et al. 1991).

In the Baie de Chaleurs (Québec/New Brunswick) and the lower north shore of Québec (QC), where both the Iceland scallop, *Chlamys islandica*, and the sea scallop, *Placopecten magellanicus*, occur, settlement has been found to be about 2,500 and 165 total spat per bag, for each area respectively (Bonardelli 1987; Chislett 1989). Settlement season occurred during September and October.

Spat collection in the Northumberland Strait occurs from late August to late October and average peak settlement varied annually from 400 to 1,100 spat per collector (Grecian et al. 2001a).

In Passamaquoddy Bay, New Brunswick (NB), spat collection has been monitored at a scallop aquaculture site since 1983 and average settlement has varied annually from 100 to 400 spat per bag (Dadswell et al. 1988; Parsons 1989; Dadswell and Parsons 1991). Settlement season was protracted, occurring from late August through to October, with a peak settlement period of 2 to 3 weeks (Dadswell et al. 1987). This site was also shown to be increasing the recruitment of scallops to the bottom directly underneath, likely from drop-off from the collection bags (Parsons et al. 1994). In a study examining the spatial distribution of spat within Passamaquoddy Bay, NB, Robinson et al. (1991, 1992) found the number of spat varied greatly throughout the bay with maximum settlement >3,000 spat per bag. Over the duration of this study, annual site specific settlement rates varied only by a factor of 2 to 3 times and spatial patterns were consistent interannually (Robinson et al. 1999).

In Mahone Bay, Nova Scotia (NS), there are two spat settlement periods each year, one in July and the other in September and October. Settlement rates initially varied from about 10 to 80 spat per collector (Dadswell and Parsons 1991, 1992a), but with the development of a commercial scallop farm in the area, spat collection has increased to over 500 spat per bag (Dadswell 2001).

16.4.3 Maximising Spat Collection

In order to minimise the uncertainty associated with the magnitude of the annual spatfall, there are several important factors, which should be considered if scallop settlement is to be maximised. First, it is axiomatic that spat collectors should be placed in an area near to or downstream from where scallops occur. Second, knowing the spawning period and duration is essential for the timing of spat collector deployment. Third, knowledge of local oceanographic currents and the settlement period of predators, such as sea stars, is an aid. Selecting areas with gyres or regions around shoals seems to assist with spat settlement (Robinson et al. 1992, 1999). Spat settlement can be further enhanced by avoiding the deployment of collectors at the surface or near the bottom (Naidu and Scaplen 1979; Bonardelli 1987; Dadswell et al. 1987). Studies have shown that biological films on the settlement substrate can enhance spat settlement (Hodgson and Bourne 1988, Parsons et al. 1990, 1993a) and that the spat bags should be pre-soaked for a couple of weeks prior to peak spatfall (Bonardelli 1987, 1988). There is, however, a trade-off in that the spat bags should not be pre-soaked for too long a period as heavy fouling will reduce settlement activity and fouling organisms will compete with scallops for food and space (e.g., blue mussels, *Mytilus edulis*). Harvey et al. (1997) demonstrated that larval scallops are attracted to chitin coated surfaces for settlement in a field experiment where they coated collectors with chitin. There were no observed differences in the sources of chitin (i.e., prawn, hydroids, crab or lobster). An additional factor to consider is the timing of the starfish (*Asterias* spp.) and gastropod (*Astarys mitrella*) settlement as they are voracious predators of the spat (Naidu and Scaplen 1979; Tetu and Davidson 2002). In Passamaquoddy Bay, NB peak starfish settlement occurs about 2 to 3 weeks prior to peak scallop settlement, hence spat collector deployment should be delayed until the peak starfish period has passed (Parsons et al. 1990; Parsons 1994) (Fig. 16.1). In Port au Port Bay, NL Naidu and Scaplen (1979) have shown that starfish settlement overlaps temporally with scallop settlement but are spatially different in their depth distribution. Thus, starfish settlement can be avoided by deploying spat bags at a greater water depth. In the Baie de Chaleurs (QC/NB) and Québec lower north shore starfish do not present a problem to aquaculturists (Tremblay 1988).

Prediction of the timing and rate of annual spatfall can be achieved with various types of monitoring protocols. The Japanese routinely monitor the occurrence of the larval pediveliger stage in order to predict settlement time (Ventilla 1982; Ito 1990). They have also found a relationship between larval abundance and spat settlement and can, based on larval abundance, predict potential number of spat per bag and determine how many spat collectors will be required to be deployed, in order to catch the quantity of scallops required each year. A larval abundance-spatfall index has yet to be developed for sea

Figure 16.1. Mean number of sea scallops per collector per two-week sampling period for 1984 to 1990 and mean number of sea stars per collector per two-week sampling period for 1986 to 1990 in Passamaquoddy Bay, New Brunswick. Vertical bars ± 1 SE. (After Parsons 1994).

scallops, but the monitoring program employed in Passamaquoddy Bay, NB entails routine sampling of the spawning stage of adults, using the gono-somatic index (ratio of gonad weight to soft body weight) as an index of spawning. Once adults have started to spawn, starfish and scallop settlement is monitored by the weekly deployment of two spat collectors. The collectors are left in the water for two weeks after which they are returned

to the lab, the contents of the bags are washed and the early settlement stages of the starfish and scallops are identified and counted. When the starfish settlement is decreasing, the annual deployment of spat collectors occurs.

16.4.4 Spat Growth

Parsons et al. (1993b) have validated an ageing technique of newly settled sea scallop spat based on a daily growth ridge formation. They reported growth rates of 32 to 57 $\mu\text{m d}^{-1}$ for postlarval scallops up to 30 days old.

Naidu and Scaplen (1979) reported a mean spat size of 12.4 mm after 10 months of growth in spat bags deployed in Port au Port, Newfoundland. Dadswell et al. (1987) have monitored the monthly growth of spat from Passamaquoddy Bay, NB. Mean shell height after 10 months of growth in suspension was between 10 to 15 mm and spat growth was found to be correlated with temperature during this period (Parsons et al. 1990). Both Naidu and Scaplen (1979) and Dadswell et al. (1987) found spat size to increase with depth of water.

A semi-annual reproductive cycle of sea scallops in Mahone Bay results in the presence of two annual spatfalls with overall enhanced spat collection and accelerated growth of the early cohort compared to the latter (Dadswell and Parsons 1992a) (Fig. 16.2).

16.4.5 Spat Sorting

After spat collectors have been left in suspension for 9 to 11 months, the scallops are large enough that they will not fall through the mesh of the bags or through the mesh of the pearl nets (intermediate culture) and their shells are hard enough that they can be handled and sorted (Dadswell and Parsons 1991). Sorting the collectors is a labour-intensive technique, which requires scallops to be hand-picked or sorted away from the rest of the settled invertebrates (other molluscs, echinoderms, worms, tunicates, etc.) (Naidu and Cahill 1986). To assist further in reducing sorting time, several companies have developed prototype spat graders (Anonymous 1991a, 1991b, 1991c), which should help to semi-automate the sorting procedure and reduce a portion of the labour component.

16.5 INTERMEDIATE CULTURE

Intermediate culture, which typically involves the use of pyramidal shaped pearl nets, trays or small mesh lantern nets, is a necessary step for raising all scallop species (Ventilla 1982; Paul et al. 1981; Wallace and Reinsnes 1984; Naidu and Cahill 1986; Parsons and Dadswell 1994, Levy 1999). Spat produced from a hatchery, due to their small size, must first go through a nursery and intermediate culture stage before final grow-out. Grecian et al. (2000, 2003) has examined several strategies for the deployment of hatchery-reared sea scallops to sea-based grow-out sites. When scallops are harvested from spat collectors, generally at an average size of about 10 mm, they are also too small for

Figure 16.2. Shell height growth of sea scallops from 1989 in Mahone Bay, Nova Scotia summer (closed circles) and autumn (open circle) cohorts grown in suspension culture. Vertical bars are ranges. Numbers beside means (circles) represent months of growth since spat settlement. (After Dadswell and Parsons 1992a).

hanging culture (ear hanging or cages), while releasing juvenile scallops directly on the bottom will result in large losses (Scheibling et al. 1991; Hatcher et al. 1996). Thus, intermediate culture is important for increasing both survival and initial growth (Imai 1977).

16.5.1 Growth

Juvenile scallops grown in pearl nets are usually held for about a year during which they attain sizes of 40 to 60 mm. Field experiments have shown that a number of factors can influence growth, namely stocking density, size, gear type, deployment time, depth, season, and location (Grecian et al. 2000, 2003).

16.5.2 Stocking Density

Growth of juveniles in pearl nets has been found to be inversely related to stocking density for sea scallops, *Placopecten magellanicus* (Dadswell and Parsons 1991; Côté et al. 1993; Parsons and Dadswell 1992; Penney 1995), bay scallops, *Argopecten irradians* (Duggan 1973; Widman and Rhodes 1991), and Japanese scallops, *Patinopecten yessoensis* (Ventilla 1982). Parsons and Dadswell (1992) found that juvenile sea scallops grown over a period of a year at densities ranging from 136 to 818 per m² had mean growth rates ranging from 0.08 to 0.11 mm d⁻¹. Dadswell and Parsons (1991) reported

similar findings for sea scallops held over shorter growing periods. Grecian et al. (2000) found no stocking density effects for very small hatchery-reared scallops; however stocking density per unit area remained low throughout their study.

A general caveat for growing scallops in pearl nets or cage culture has been to never grow scallops at densities occupying more than a third of the floor space (Taguchi 1978; Mottet 1979; Paul et al. 1981), the implication being that growth will be compromised under crowded conditions. Parsons and Dadswell (1992) found, however, that juvenile sea scallops grew at densities equivalent to 115% of the floor area and exhibited substantial growth at densities of up to 50% or 60% of the floor area (Fig. 16.3). Densities of 80–90 11-mm spat per pearl net were recommended by Gaudet (1994) for large scale intermediate culture operations in the Iles-de-la-Madeleine. A study by Côté et al. (1994) demonstrated that reduced growth in suspended culture is due to the effects of food depletion by the scallops in the crowded conditions and not the physical effect of the crowding. In a related study, Claereboudt et al. (1994) also showed that the decrease in flow within pearl nets resulted in an increase of growth and somatic tissue of the caged scallops due to the more optimal flow regime. This effect probably persists until density dependent factors begin to predominate.

Figure 16.3. Percent areal floor coverage of pearl nets by the sea scallop at various stocking densities over a year's growth in intermediate suspension culture (After Parsons and Dadswell 1992).

16.5.3 Depth

The depth at which pearl nets are suspended in the water column can also result in substantial growth differences for juvenile sea scallops. In an experiment in which pearl nets were variously suspended from 5 m off-bottom to 0.25 m off-bottom Dadswell and Parsons (1991) found that the mean size of juveniles ranged from 54 to 42 mm, respectively. Growth differences of this magnitude were similar to the effects of stocking density as determined by Parsons and Dadswell (1992). The effect of suspension depth on growth in sea scallops and other species of scallops has been attributed to differences in food level (Wallace and Reinsnes 1984; Côté et al. 1993; Frechette et al. 2000). In a study done in both an open and sheltered location in the Iles-de-la-Madeleines, scallop spat were found to grow and survive better in pearl nets that were grown near the surface (Gaudet 1994). Côté et al. 1993) found that spat grew better at 9 m than at 21 m and was related to the levels of food in the 0.7 to 5.0 μm size range, although density effects masked some of the trends. From the above observations we can see there is likely no one depth that will be suitable in all locations. The optimum culture depth for a particular location will depend on the distribution of the food in the water column and the depth to which wave action will impact the suspended culture gear. There may also be interactions with other fouling species that may be depth dependent (Claereboudt et al. 1994; Grecian et al. 2000).

16.5.4 Season

Parsons and Dadswell (1992) and Grecian et al. (2000) reported a decreased growth rate in juvenile sea scallops during the winter. Seasonal effects on growth were, as would be expected, related to the annual variation in temperature and food levels. In many areas within the distribution range of *Placopecten*, winter water temperatures can drop to 1°C.

16.5.5 Location

A number of studies throughout the east coast of Canada have examined growth rates of juvenile scallops held in suspension. Naidu and Cahill (1981) reported growth rates of 0.096 mm d⁻¹ for Spencer's Cove, NL. Dadswell and Crawford-Kellock (1989) and Dadswell and Parsons (1991, 1992b) found growth rates of 0.12 to 0.18 mm d⁻¹ during the autumn for scallops of age 1+ grown in Mahone Bay, NS and Dadswell and Parsons (1992a) reported a remarkable 0.33 mm d⁻¹ for juvenile scallops from the summer settlement period (i.e., the June-July spawning) during the first six months of the second year. Growth rates of 0.098 to 0.117 mm d⁻¹, 0.12 mm d⁻¹ and 0.084 to 0.111 mm d⁻¹ have been reported for Passamaquoddy Bay, NB by Wildish et al. (1988), Dadswell and Parsons (1991) and Parsons and Dadswell (1992), respectively. These growth rates are remarkably similar given the broad geographic area. One of the reasons for this might be that certain density thresholds of scallops were not exceeded that could have resulted in food depletion of the local seston fields. There is an optimal relationship between flow rate and seston concentration in the feeding dynamics of sea scallops (Wildish and

Saulnier 1992). As with stocking density and depth, spatial differences in growth of scallops, held in suspension and grown on the bottom, have been attributed to variations in food and temperature (MacDonald and Thompson 1985a, 1985b, 1986).

16.5.6 Survival

Survival of scallops was independent of stocking density for sea scallops (Côté et al. 1993; Parsons and Dadswell 1992). Parsons and Dadswell (1992) found a mean survival of 91% and attributed the 9% mortality to initial handling methods. In another study, Dadswell and Parsons (1991) reported a survival of 57%; the higher mortalities may have been due to the repeated handling of scallops. Survival rates have been linked to initial spat size at seeding (Penney and Mills 1996) for scallops grown to 60 mm in lantern nets; mesh size was not found to be a significant factor.

16.5.7 Gear Selection

Pearl nets have almost exclusively been used for the intermediate culture of all scallop species (Taguchi 1978; Ventilla 1982; Naidu and Cahill 1986; Bourne et al. 1989). Dadswell and Parsons (1992b) have evaluated the handling performance and cost associated with several different net designs (Table 16.1). The total cost associated with raising 100,000 scallops ranged from \$1,684 to \$3,666. Two of the gear types (Shibetsu and Lantern nets) that were the easiest to handle were also the most expensive to purchase. This preliminary study did not, however, examine the long-term growth and survival of scallops for the different nets.

Table 16.1

Handling times and costs associated with growing 100,000 sea scallops, *Placopecten magellanicus*, in intermediate culture for several different net designs (from Parsons and Dadswell 1994).

Net Type	Loading Time (hr)	Unloading Time (hr)	Total Time (hr)	Labour Cost (\$) ¹	Cost of Gear (\$) ²	Total Cost (\$) ³
Pearl-square (9 mm)	104.2	33.8	138.0	966	1,860	2,826
Pearl-square (6 mm)	104.2	42.6	146.8	1,028	1,810	2,838
Pearl-square (3 mm)	132.3	64.8	197.1	1,380	2,050	3,430
Pearl-round (6 mm)	125.3	37.0	162.3	1,136	2,530	3,666
Superlantern	133.3	25.0	158.3	1,108	2,530	3,638
Shibetsu	47.9	17.5	65.4	458	3,090	3,548
Lantern	92.6	7.7	100.3	702	2,734	3,436
Oyster Tray	83.3	14.4	97.7	684	1,000	1,684

1. Based on an hourly rate of \$7.00.

2. Based on a stocking density of approximately 180 scallop m⁻² and amortised over 5 years.

3. Total cost = labour cost + amortised cost of gear.

16.5.8 Strategies for Intermediate Culture

There are a number of competing factors to consider when developing an overall strategy for intermediate culture. The type of gear chosen appears to be a trade-off between ease of handling (labour) and the cost and durability of the gear. Handling of nets (single or repeated) must be weighed against cleaning the nets to reduce fouling (increased growth and labour) (Cole et al. 1996; Devaraj and Parsons 1997) and increased mortality associated with repeated handling. Some of the handling due to fouling can be reduced by avoiding areas that are conducive to higher settlement rates by undesirable species. Culturing techniques in Japan recommend limiting handling nets to two times a year compared to the traditional four times a year (Taguchi 1976; Ventilla 1982). As well, the deployment time of gear is critical to maximising growth and avoiding predators such as starfish (Levy 1999, Grecian et al. 2000; Grecian et al. 2003) (Fig. 16.4).

The 'best' stocking density for growing scallops in intermediate culture is also a trade-off between reduced growth rates at high densities and a large number of nets (high cost) at lower stocking densities (Parsons and Dadswell 1992). Growth rates can be intentionally manipulated to ensure a continuous supply of the desired size of scallops in order to maximise efficiency of gear use and or to support continuous market supply. It may also be desirable to manipulate growth rates based on the choice of stocking density as influenced by the depth / food levels (Frechette et al. 2000), timing of transfer to final grow-out (ear hanging or cages), desired final market product (meat or whole animal) and or market size (e.g., princess scallop versus meats only).

Figure 16.4. Mean shell height of scallops deployed over five consecutive two-week intervals in 1997 (short-term) and on November 8, 1997 (Autumn) and June 24, 1998 (spring) at Poole's Cove, Newfoundland. The initial date of an interval was the final date of the previous short-term interval. Common letters denote no significant difference among shell heights for each sampling period (Tukey's b test). Vertical bars are $\pm$ SE. (After Grecian et al. 2003).

16.6 FINAL GROW-OUT

Scallops are removed from intermediate culture at a size of about 40 to 60 mm (from 16 to 26 months of age) for final grow-out to market size. There are two basic methods for the final grow-out of scallops, suspension culture and bottom seeding (also known as enhancement, sowing, planting or relaying) (Mottet 1979; Ventilla 1982). Suspension culture takes about 0.5 to 2 additional years to reach market size, whereas bottom grown scallops require a further 2 to 3 years.

16.6.1 Suspension Culture

Suspension culture can entail the use of cages (e.g., multi-tiered Lantern nets) or ear hanging. Traditionally, these types of nets were relatively small so that they could be handled easily by a single person, although they could have up to 20 different levels within. More recently in eastern Canada, larger scale cages have been designed to grow larger numbers of animals in a single unit in an attempt to design a system that was more applicable to automation (Parsons et al. 1998). These larger cages are either larger versions of lantern nets or they are stackable plastic trays mass produced through injection moulding systems. There is a significant relationship between the mesh-size of the tray and the flow rates through the tray (Brake and Parsons 1998) so growers should carefully match the trays to their existing conditions. To date, however, the performance of these new trays or large cages has not been fully evaluated over several growth cycles.

Ear hanging consists of hanging scallops (>50 mm shell height) by their "ear" or auricle. A small hole is drilled into one of their ears or in the byssal notch and the scallops are then either threaded onto loop cord or stuck on a barbed plastic "aggie" pin, which has been inserted through a piece of braided rope (Bourne et al. 1989). A commercial ear hanging machine has become available for semi-automating the ear hanging procedure (Anonymous 1991a, 1991c). Loop cord consists of a piece of braided rope, which contains loops of 1 to 2 cm which are evenly spaced about 10 to 15 cm apart (Dadswell and Parsons 1991). Scallops are then threaded onto the loop with a piece of nylon monofilament. Separation of the "aggie" pins is usually about 15 cm.

16.6.2 Bottom Culture

Bottom culture involves seeding scallops directly on the bottom and is also known as "enhancement". The type of bottom required for this type of operation should be consistent with the physical and biological qualities that comprise traditional scallop beds (see Stokesbury and Himmelman 1995). As a result, this implies that the traditional fishermen typically will be involved with most of these broad-scale initiatives. Ultimately, some form of property rights or limited access to the resource will have to be established if private investment is being sought. A large leased area is necessary if a substantial number of scallops are to be cultured. For example, if 1,000,000 scallops are to be seeded annually on the bottom at a density of $5 \cdot \text{m}^{-2}$, 20 ha yr^{-1} would be required. In Mutsu Bay, Japan 23,000 ha are used for bottom culture by co-operatives (Ventilla 1982).

The one main advantage of bottom culture over suspension culture is its low capital cost (Frishman et al. 1980; Wildish et al. 1988). There are, however, several disadvantages; growth rates are slower, sea scallops are capable of swimming and could potentially swim off a lease site (Caddy 1968; 1989; Parsons et al. 1992b), and scallops are highly susceptible to predation (Elner and Jamieson 1979; Jamieson et al. 1982; Barbeau and Scheibling 1994a, b; Barbeau et al. 1998). Losses of 20 to 50% are routinely experienced in Japanese scallop culture after 2 to 3 years of growth on bottom (Taguchi 1976; Ventilla 1982). These losses are due primarily to predation, although dispersion of a seeded population was relatively rapid in a shallow water site in Nova Scotia (Scheibling et al. 1991; Hatcher et al. 1996). Several studies have shown that predation rates are highest shortly after the seeding operation and that as prey density increases so does the predation rate, although not predator numbers (Barbeau et al. 1996; Barbeau et al. 1998; Wong et al. 2001). Crabs and starfish have been the major predators identified to date, each having different behaviour patterns that are also affected by temperature (Barbeau and Scheibling 1994a, 1994b) and substrate (Wong and Barbeau 2003). Enhancement efforts in the Iles-de-la-Madeleine, Québec have shown that 94–99% of the scallops seeded on the bottoms in some areas have been lost (Cliche et al. 1997; Nadeau and Cliche 1998). The seeding strategy, time of year, scallop condition and predators all played a role in the loss of the seeded scallops. At this site, there appeared to be relatively little dispersal of scallops from the general area of the seeded sites based on a combination of diving and video techniques on tagged scallops (Cliche et al. 1994). To help understand the population dynamics of the seeded juveniles, some mathematical models have been developed for the process (Barbeau and McDowell 1998; Barbeau and Caswell 1999).

16.6.3 Growth

Both the shell and meat growth rates of scallops grown in suspension are faster compared to bottom culture. Both Naidu and Cahill (1978) and MacDonald (1986) have reported final annual growth rates of $0.06 \text{ mm} \cdot \text{d}^{-1}$ for sea scallops from Newfoundland whereas MacDonald (1986) reported a growth rate of $0.044 \text{ mm} \cdot \text{d}^{-1}$ for bottom grown wild scallops. Bottom cultured and wild scallops from Passamaquoddy Bay, NB and the Bay of Fundy, NB each had annual growth rates of $0.06 \text{ mm} \cdot \text{d}^{-1}$ (Wildish et al. 1988; Chandler et al. 1989). In Passamaquoddy Bay, scallops grown in cages and by ear hanging had annual growth rates of $0.072 \text{ mm} \cdot \text{d}^{-1}$ and $0.08 \text{ mm} \cdot \text{d}^{-1}$, respectively (Wildish et al. 1988; Dadswell and Parsons 1991). Grant et al. (2003) also found scallops grown by ear hanging out performed those grown in cage culture.

Shell growth rate height was inversely related to stocking density. Naidu and Cahill (1978) reported shell heights of 93.3 to 71.7 mm for scallops grown in cage culture at densities of 10 to 50 scallops. In an experiment in which scallops were cultured by ear hanging on loop cord, Dadswell and Parsons (1991) found no significant difference in growth between scallops, which were spaced 5 and 10 cm apart.

Growth of scallops, as measured by meat yield, was also greater in scallops cultured in suspension compared to bottom grown ones; 90 mm scallops from Passamaquoddy

Bay, NB and the Bay of Fundy, NB had meat weights of 10.4 g and 5.0 to 8.1 g, respectively (Jamieson and Lundy 1979; Chandler et al. 1989). Scallops cultured in cages and by ear hanging in Passamaquoddy Bay, NB had meat yields of 11.2 g and 16.3 g, respectively (Wildish et al. 1988; Dadswell and Parsons 1991) and in Mahone Bay, NS, suspended scallops averaged 15.0 g for meat weight (Dadswell and Parsons 1992a). This represents a 7.7 to 47.1% increase in meat weight for a similar size scallop grown in suspension versus a bottom grown animal. MacDonald (1986) reported similar differences in the somatic weight of suspended and bottom grown scallops from Newfoundland. Seasonal differences are also found in the relative weight of the different organs (i.e., gonad, adductor muscle) in cultured scallops (Penney and McKenzie 1996).

From a comparison of growth rates and meat yields of sea scallops by ear hanging (Dadswell and Parsons 1991) and cage culture (Wildish et al. 1988), it would appear that the ear hanging technique produces faster growing scallops with a greater meat yield.

16.7 SCHEDULING AND STRATEGIES

The timing and co-ordination of the different culturing stages is contingent upon cost factors and equipment availability but also type of products to be marketed (e.g., whole animal versus meat only) and continuity of supply. This requires that different sized scallops (e.g., 50 mm and 90 mm) be available throughout the year. Since the availability of spat is presently restricted to the summer (Dadswell and Parsons 1992a) or autumn (Dadswell et al. 1987), ensuring a continuous supply of certain size scallops entails manipulating their stocking density at intermediate and or final grow-out stages to enhance or slow down their growth, which will result in a staggered supply of appropriate sizes.

The typical scheduling of events includes in "Year 1" monitoring of spawning and starfish and spat settlement in the summer and spat collector deployment in the autumn (~30 days after spawning). "Year 2" involves sorting spat in the early summer when they are large enough to handle and immediately placing them in pearl nets. In the autumn the nets will be required to be thinned and cleaned, especially if the pearl nets were stocked with high densities of scallops (100 to 200/net). In the summer of "year 3", when the scallops are 24 months old and have reached about 50 mm, they will be ready to either market as whole animals (princess scallops) or be placed in final grow-out (ear hanging or cage culture). In the summer of "year 4" at approximately 36 months of age, the scallops can be harvested for roe-on meats and in the autumn for meats only.

16.8 SITE SELECTION

Site selection criteria are an integral component to the success of any aquaculture venture. Criteria can be viewed on two different scales, a large and small scale. In general, features on a large scale share characteristics in the order of 10 to 100 km, whereas small scale features vary on the order of 0.1 to 1 km. In other words, some bodies of water share common traits, such as a bay being completely covered with ice in the winter, whereas within a bay, a local promontory may have better current

characteristics for spat collection and scallop growth than an open water site. Site selection criteria can also be generally applied to all aspects of scallop aquaculture or be specific to certain phases, such as spat collection.

16.8.1 Environmental Criteria

16.8.1.1 Temperature and salinity regime

Fluctuations in temperature and salinity for a particular site should be within acceptable ranges as obviously there will be seasonal cycles present. Sea scallops tolerate temperatures of 0 to 18°C and salinities of 25 to 32‰ (Dickie 1958; Frenette et al. 2002; Frenette 2004), but some acclimation is possible by the animals (Dickie 1958). Bergman et al. (1996) reported that salinities at 16‰ and below were lethal and that salinities between 16 and 21‰ put scallops into catatonic shock at 1°C. Preferred temperatures are likely close to 12°C and salinities over 31‰. Particular attention should be paid to the extreme values, i.e., the temperature should not exceed 18°C during the summertime nor should salinity drop below 25‰, especially during spring run-off. Temperature can affect the severity of the physiological response to environmental stressors such as heavy metals (Nelson et al. 1977) and also behavioural escape responses (Dickie and Medcof 1963).

16.8.1.2 Ice coverage

Ice coverage may restrict access to sites during the winter and all lines and floats will have to be submerged. Similarly, if ice flows are present, lines and floats will have to be submerged. Generally, it is a good practice to submerge sites during the winter to avoid storm damage and wear on gear.

16.8.1.3 Wind

The seasonal prevailing wind pattern and fetch should be considered, as certain exposures are more susceptible to wind generated wave and turbulence. Scallops do not grow well under strong wave action or in areas with high concentrations of suspended sediment (particulate inorganic matter) (Frenette 2004). Submerging the head ropes to 2 to 4 m below the surface will generally decrease turbulence. On very exposed sites, even benthic cultured scallops can suffer abrasion due to the movement of gravel and sand etc. (Miyake et al. 1995).

16.8.1.4 Bottom type

Bottom type is especially important if bottom culture is being considered. Scallops live mainly on gravelly or sandy substrates and not on muddy bottoms (Stokesbury and Himmelman 1995). Selection of a poor bottom will result in emigration of scallops, particularly sand (Stokesbury and Himmelman 1996). Movement of 10 to 15 km are not uncommon (Melvin et al. 1985).

16.8.1.5 Turbidity

Scallops are sensitive to the amount of suspended particulate matter in the water, but are capable of maintaining high growth rates by increasing their feeding rates for short periods of time (Cranford 1995). Obviously, benthic animals have evolved to deal with a certain amount of re-suspension events due to bottom turbulence. Several different species of both terrestrial and marine sources of seston have been identified from scallop gut contents (Shumway et al. 1987) and several studies have showed that scallops are able to actively select high-quality chlorophyll-containing particles (Shumway et al. 1985; MacDonald and Ward 1994). However, if the inorganic component of the seston reaches levels in excess of 2 mg dm^3 , then labial sorting begins and the production of pseudofaeces was initiated followed by reductions in growth (Cranford and Gordon 1992). Phytoplankton has been demonstrated to be a better food source than “aged” kelp particles in laboratory studies (Cranford and Grant 1990; Grant and Cranford 1991) and therefore, scallops often have better growth rates higher up in the water column (Emerson et al. 1994). However, mixed results were found in Lunenburg Bay in Nova Scotia where bottom cultured scallops sometimes showed greater growth rates than those in suspension culture (Kleinman et al. 1996). They also found spatial differences between site in growth rates. Frenette et al. (2001) and Frenette (2004) found poor scallop growth in shallow-water embayments of southeastern New Brunswick, which had high turbidity.

16.8.2 Biological Constraints

16.8.2.1 Predators

The presence of predators is again of primary interest if bottom culture is being considered. The main species to consider are starfish (*Asterias* spp.), wolffish (*Anarhichas lupus*), lobsters (*Homarus americanus*) and rock crabs (*Cancer irroratus*) (e.g., Dickie and Medcof 1963; Elner and Jamieson 1979) (see also section 16.6.2). Predators may be reduced or avoided altogether in suspension culture by good husbandry practises (i.e., keeping nets and ear hanging lines off the bottom).

16.8.2.2 Fouling organisms

Fouling organisms are generally ubiquitous and have to be tolerated. The best control against fouling is to determine settlement times of the main fouling organisms and then plan the scheduling of the different culturing phases accordingly (pearl net and cages). Some degree of control can also be gained by deploying nets deeper in the water. In some regions, settlement of fouling organisms is negligible at depths greater than 10 m.

16.8.2.3 Phycotoxins

When considering the production of princess scallops, the presence and seasonality of phycotoxins need to be taken into account. Toxins in scallops are a risk to consumers and

testing is required to ensure product safety (Shumway et al. 1988). The occurrence of toxic algae are generally known for certain bodies of water (e.g., Bay of Fundy - Gulf of Maine, Gulf of St. Lawrence) although the species may vary as well as their mode of action (Prakash et al. 1971; Medcof 1985; Gainey and Shumway 1988; Martin and White 1988). The consumption of high levels of toxic algae has been shown to negatively affect the growth rate of scallops (Chauvaud et al. 1998). The implications of toxic algae on culture and fisheries have attracted several reviews (i.e., Shumway et al. 1988; Desbiens et al. 1990; Shumway 1990; Shumway and Cembella 1992).

Paralytic shellfish poison (PSP) toxin has been reported in *Placopecten magellanicus* for several many years (i.e., Bourne 1965; Hsu et al. 1979; Jamieson and Chandler 1983; Cembella et al. 1994) and is a feature that must be accommodated in the culture protocols. However, small-scale differences in the occurrence and concentration of toxin in bivalves do occur (White 1988; Robinson et al. 1999; Parsons et al. 2002). *P. magellanicus* has been categorised as a slow detoxifier of the saxitoxin (PSP) from the dinoflagellate *Alexandrium fundyensis* taking from months to years to detoxify.

Amnesic shellfish poison (ASP) or domoic acid is a neuro-toxic amino acid that can be produced by the marine diatoms *Nitzschia* (= *Psuedo-nitzschia*) *pungens* (Subba Rao et al. 1988; Maranda et al. 1990) and *Nitzschia pseudodelicatissima* (Martin et al. 1990). Gilgan et al. (1990) reported on the distribution and magnitude of domoic acid in Atlantic Canada in 1988. Haya et al. (1991) reported on the domoic acid levels in shellfish and phytoplankton from the Bay of Fundy. It has been reported from scallops (Bird and Wright 1989).

Another potential toxin, diarrhetic shellfish toxins (DSP) cause gastrointestinal distress in humans and scallops can acquire DSP toxins by ingesting toxic dinoflagellates (such as *Prorocentrum lima*) from the water column or from benthic seston (Yasumoto et al. 1984). These species are recognised to be a hazard to consumers and therefore culture and fisheries operations (i.e., Dahl and Yndestad 1985; Freudenthal and Jijina 1988).

16.8.2.4 Diseases and parasites

The scarcity of parasite and disease related problems in the sea scallop bodes well for aquaculturists (see Chapter 11). However, because scallop culturing can be intensive, the culture conditions may amplify any of the natural diseases present. At the present time, there is not a good understanding of the endemic parasites and diseases that currently affect the local scallop populations (*Placopecten*, *Chlamys* and *Argopecten*) (Ball and McGladdery 2001), but databases are being developed. For example, rickettsia-like organisms were found to infect the gills and plicate membranes of sea scallops near Rhode Island and were found to be quite contagious and species-specific with uninfected individuals (Gulka and Chang 1985). However, the health impacts to the scallop could not be determined. Maintaining an awareness of any potential causative agents and eliciting the co-operation with various agencies (government, universities and industry) may ensure a relatively disease free operation (McGladdery 1990). In addition, certain challenge tests are being developed to evaluate the responses of scallops to potential pathogens (Belvin et al. 2001; Roussy et al. 2001).

16.9 PRODUCTS AND MARKETING

Of the approximately 350 species of extant scallops, only about twelve are commercially fished or cultured on a large scale and the bulk of the world output is consumed by only a few countries, mainly, USA, Japan and Western Europe (De Franssu 1990). In North America, the principal product of the commercial sea scallop fishery has been the meat only. The landed processed product is then either sold fresh or frozen, with the USA being the largest consumers of this product (Department of Fisheries and Oceans 1989). Individual Quick Frozen (IQF) meats are rapidly dominating the market in North America. In Canada the bulk of the scallops from the commercial fishery are exported to the USA as meats, but throughout the last forty years, scallops with the roe-on have been periodically marketed (Bourne and Read 1965; Jamieson 1979; Department of Fisheries and Oceans 1989). The primary destination of this product has been to France (Dupouy 1983; De Franssu 1990).

Sea scallop culturists have shown a desire to produce three products: meats, roe-on meats and whole animals (~50 to 70 mm). Taste panel assessments could not differentiate between cultured and commercial caught scallops, thus a cultured sea scallop product is expected to receive consumer acceptance (Naidu and Botta 1978). Thus far, whole animals have been marketed in Québec, Ontario and New England (USA) and fresh meats have been sold locally or regionally. Regulatory agencies have established a protocol for testing whole animals and roe-on meats to ensure that these products are free of phycotoxins and bacterial pollution. If growers can successfully market whole animals and roe-on meats, cash flow can be increased through the sale of smaller animals; however, shelf life of live whole scallops is limited.

The market for meats of sea scallops demands a quality product with prices primarily determined by the size of the commercial catch (i.e., supply) (Lines 1988). Aquaculturists can deliver a high quality, fresh product as access to farms and market-size scallops are generally close to the main markets and the product is available year-round.

16.10 ECONOMICS

The main constraint to larger scale development is that it is a capital and labour intensive venture with relatively long grow-out period (>3 years from egg to minimum meat market size). The main capital costs are primarily associated with the gear, i.e., pearl nets and lantern cages. Certain husbandry practices, however, can reduce costs. For spat collection, used monofilament gillnetting is usually readily available from the commercial fishery and for final grow-out using ear hanging, the main cost is associated with purchasing the "aggie" pins and rope (exclusive of the drill or ear hanging machine).

Labour, another large component of a culture operation, is centred on each of the culturing steps and occurs at different times of the year. A large amount of labour is required to sort spat, load and thin pearl nets and lantern nets, clean nets, ear hang the scallops, and harvest the product. Savings can be gained depending upon the type of gear used (e.g., easy loading nets, (Dadswell and Parsons 1992b)) and strategy employed (e.g., using a low initial density for intermediate culture thereby reducing the need for thinning

(Parsons and Dadswell 1992)). Any form of mechanisation that a grower can utilise will assist the operation (e.g., pressure cleaning, spat sorter, spat grader).

Several economic analyses have been conducted on the different grow-out strategies (e.g., bottom culture, cage culture and ear hanging). Based on the high cost of labour and gear and the price for meat only, the early economic scenarios were marginal at best (Frishman et al. 1980; Gilbert and Cantin 1987; Wildish et al. 1988).

An economic assessment by Ford (1997), however, highlighted that scallops grown in suspension had a larger meat yield to shell size than allowed for in earlier meat market assessments. This adjustment to the economic model, combined with growing scallops to a larger meat size (weight), indicated that an economically viable industry could be realised based on a meats only product; a less risky market in North America than a roe-on or whole animal market. If a consistent whole animal or roe-on meat product could be established in the market, then yield per scallop, cash flow and revenues would increase (De Franssu 1990; Dadswell and Parsons 1992a; Ford 1997). Studies in Passamaquoddy Bay, NB and Mahone Bay, NS have also shown that with experience both growth rates and efficiency have improved over time (Dadswell and Parsons 1991, 1992a).

The modelling exercise conducted by Penney and Mills (2000) reported on a 2-year pilot-scale study and concluded that vertically-integrated farms seeding 1 million spat annually were economically viable. Sensitivity analyses indicated that sale price for the harvested product was key. Other variables such as capital costs, labour and mortality were not as sensitive.

16.11 SOCIAL ISSUES

There has been some reluctance on the part of the regulating agencies and the general coastal communities in eastern Canada to embrace the concept of scallop aquaculture. This occurs at a number of administrative levels and for a number of reasons; not the least being an active wild fishery that is concerned about competition for markets and for space. In a report on the environmental requirements for sea scallops in eastern Canada, the limiting factor for scallop culture in the coastal areas was reported to be coastal sewage/faecal pollution and toxic phytoplankton (Stewart and Arnold 1994). While these reasons have hindered scallop culture and can be limiting, depending upon the product being produced (i.e., meats vs. roe-on), it is only part of the story. In general, there are only two marine species that are being grown in large amounts in Eastern Canada, the blue mussel (*Mytilus edulis* and *M. trossulus*) and the Atlantic salmon (*Salmo salar*). The production levels of both of these species have grown quickly and are now nearing peak capacity in many areas. This has resulted in resource use conflicts with other users such as the fishery, recreation and tourism industries. There are also concerns about the potential environmental effects that may be occurring at some of the culture sites. All of these issues can influence the perception of local coastal residents as to how other culture industries may evolve and has sometimes increased the level of local concern. As the existing industries look for ways of continually expanding and with requests for marine leases from a new culture candidate, one solution to address public concern is to do a better job at integrating the culture into the local economy and society (e.g., Parsons et al.

2002). Starting small and scaling up is probably a good approach with the appropriate checks and balances built in to the development plan. Bivalve culture often takes a significant amount of space (10–20 ha per operation) so the challenge will be to devise methods to intensify the culture while maintaining the long-term sustainability of the site.

16.12 FUTURE PROSPECTS

There is a strong demand for scallops (De Franssu 1990). However, the economic feasibility of sea scallop culture is marginal at best. As the commercial culturing of sea scallops develops and increases in size, it will move further along the “learning scale” and become more efficient. As operations become larger they will benefit from the “economy of scale”, i.e., increased volume/decreased costs, and with the development of new technologies or approaches, such as the ear hanging machine and spat sorters or new approaches (e.g., triploidy (Jackson et al. 2003) or low cost, reliable hatchery production), significant savings on labour may accrue. The medium term outlook is a modest commercial industry in Atlantic Canada that could increase if it can realise a premium product for the marketplace.

ACKNOWLEDGMENTS

Our thanks to Sharon Ford for reviewing the chapter.

Chapter 17

Bay Scallop and Calico Scallop Fisheries, Culture and Enhancement in Eastern North America

Norman J. Blake and Sandra E. Shumway

17.1 INTRODUCTION

Scallops are commercially important shellfish worldwide (Table 17.1) with the average total catch between 1988 and 1997 at 522,894 pounds of meats (FAO 1997). Five species (sea scallop, *Placopecten magellanicus*; Icelandic scallop, *Chlamys islandica*, calico scallop, *Argopecten gibbus*; bay scallop, *Argopecten irradians*; weathervane scallop, *Patinopecten caurinus*) contribute to the major wild fisheries in North America with minor fisheries for two other species (pink scallop, *Chlamys rubida* and spiny scallop, *Chlamys hastata*).

Aquaculture and enhancement efforts are still limited activities in North America but world aquaculture of all scallops exceeds 1.7 million metric tonnes (O'Bannon 1999). Where scallop aquaculture activities do occur in North America, they contribute substantially to the local economies. Further, production from domestic activities (fisheries, aquaculture and enhancement) does not totally meet supply requirements and scallops are regularly imported from other countries and comprise about 40–80% of the total United States supply (Table 17.2).

This chapter is intended to present an overview of calico and bay scallop fisheries, aquaculture and enhancement efforts in eastern North America. Sea scallops are covered in Chapters 15 and 16 and west coast species are covered in chapter 18.

17.2 FISHERIES

17.2.1 Bay Scallop, *Argopecten irradians*

17.2.1.1 Distribution

The bay scallop, *Argopecten irradians* (Lamarck), occurs in the shallow (<10 m), protected estuarine habitats along the east coast of the United States (Fig. 17.1) from Cape Cod, Massachusetts to Texas (Clarke 1965). Three subspecies have been described based upon shell morphometrics (Waller 1969). The northern subspecies, *Argopecten irradians irradians*, extends from Cape Cod to approximately New Jersey and Maryland where it may hybridise with the southern bay scallop, *Argopecten irradians concentricus* (Clarke 1965). Populations of the southern bay scallop of sufficient size to harvest become discontinuous about North Carolina. It is absent along the Georgia coast (Walker et al.

1991) and from the east coast of Florida (unpub. data). It reappears on the southwest coast of Florida in Florida Bay and continues north along the west coast to Pensacola. Although not common, the southern subspecies reportedly is found as far west as Louisiana (Waller 1969; Broom 1976). The third subspecies, *Argopecten irradians amplicostatus*, occurs in the western Gulf of Mexico (Waller 1969). The degree to which these subspecies are physiologically different is not well understood (Bricelj et al. 1987) but Blake et al. (1997) have shown that there are significant genetic differences.

17.2.1.2 Biology

Bay scallops are functional hermaphrodites, which reproduce essentially once during their 12–24 month life span. Spawning is largely catastrophic, although the northern populations are more synchronous than the southern subspecies (Barber and Blake 1991).

The northern subspecies from New York spawn from June through August (Bricelj et al. 1987) while the Massachusetts populations spawn May through July (Taylor and Capuzzo 1983). In North Carolina, bay scallops spawn from July through August (Sastry 1968). On the west coast of Florida, the southern subspecies spawns in early August in the north (Sastry 1961) and October in the south (Barber and Blake 1983). Little has been reported about the spawning of the subspecies *A. irradians amplicostatus* in the western Gulf of Mexico. See Chapter 6 for a more detailed discussion of scallop reproduction.

The planktonic larval stage lasts 12–14 days (Sastry 1965), and it is during this planktonic stage that the larval distribution and eventual recruitment may be controlled by the hydrodynamics of the estuary (Eckman 1987). As the larvae metamorphose, the prodissoconchs (190 μm) typically attach to blades of seagrass. Growth during the winter is slow but by early spring scallops of 20–25 mm can be seen on the seagrass (Barber and Blake 1983). By late spring scallops become unattached and settle to the bottom at which time growth becomes rapid. Scallops of 40–50 mm occur by summer and may reach 60–90 mm by early winter (approximately 16 months of age). Growth is continuous in the Florida subspecies even at 33°C, only 2°C below the upper lethal temperature of the

Figure 17.1. Distribution of scallops (*Argopecten* sp.) in eastern North America.

adults (Sastry 1961). Natural mortality after 12 months of age is high due to senescence, and only a few survive into the winter months of their second year.

17.2.1.3 Fishery

Landings are highly variable among years and among the various sections of the eastern United States (Table 17.3). The populations are dependent upon natural recruitment for continuation, although some enhancement efforts have been attempted. In 1985, bay scallop populations in the northeast were decimated by blooms of a previously unknown microalga, *Aureococcus anophagefferens* ("brown tide") (Tettelbach and Wenczel 1993). Three successive years of algal blooms resulted in virtually all-native stock in the Peconic Bays and the New York fishery being essentially eliminated. In addition, eelgrass beds were also depleted, thus reducing the total area of suitable habitat for scallop settlement. Landings for 1998 were 105,000 pounds of meats valued at \$US 368,000 (Fig. 17.2). This represents an increase of 33,000 pounds (46%) and \$58,000 (19%) compared with 1997 (O'Bannon 1999). The average ex-vessel price per pound of bay scallop meats was \$3.50 in 1998 compared with \$4.31 in 1997. Meat counts range between 50 and 100 per pound. Total catch and landed values from 1950–1999 are presented in Table 17.3 and Fig. 17.2.

Commercial fishing records for *A. irradians* date back to 1858 (Ingersoll 1886) and the introduction of the dredge in 1874. Commercial fishing for *A. irradians* is strictly limited and there is a large recreational fishery. In most areas, harvest is usually limited to the months of August–December. The bay scallop fishery is a protected resource throughout the range of the species. Commercial harvest of the species was prohibited in Florida waters in 1995.

Scallops are usually collected by diver, handpicking or rake. Some fishermen use small boats equipped with outboard engines and one or two small dredges. Scallops are culled on board and only the meats are presently harvested. Catch limits are determined on a season-by-season basis by fisheries officials in accordance with population fluctuations (Rhodes 1990; 1991).

17.2.2 Calico Scallop, *Argopecten gibbus*

17.2.2.1 Distribution

The calico scallop, *Argopecten gibbus*, is largely restricted to the sub-temperate and tropical waters of western North Atlantic (Fig. 17.3) with the major stocks distributed from Cape Hatteras, North Carolina to the Cape San Blas area of the northeastern Gulf of Mexico (Waller 1969). Calico scallops have also been collected from the Greater Antilles, Bermuda, and the western portions of the Gulf of Mexico (Waller 1969) but stocks of commercial importance have not been reported from these areas. At least one other species, *Argopecten circularis*, is commonly called a calico scallop and is harvested in the Republic of Panama.

Argopecten gibbus, inhabits the relatively shallow waters of the continental shelf and upper slope out to reported depths of 370 m (Waller 1969). Major commercial stocks along the Atlantic and Gulf coasts are usually located in depths of 20–50 m on hard sand bottom.

Figure 17.3. Landings and value of calico scallops, *Argopecten gibbus*. Data from NMFS (pers. comm.) and Florida Marine Research Institute, Fishery Dependent Monitoring Program.

17.2.2.2 Biology

The calico scallop, like the bay scallop, is a functional hermaphrodite. The species exhibits two spawning periods during each calendar year when optimal environmental conditions occur (Moyer and Blake 1986). The first and predominant spawn of the calendar year occurs in late spring from April to June. This follows the accumulation of gonadal reserves during the winter months. When spawning does occur it is rapid and often complete. A large percentage of any subpopulation normally spawns over a 1–3 week period.

The second reproductive cycle of the calendar year begins with an accumulation of gonadal reserves in July and August with spawning occurring in late summer to early autumn. The “fall spawn” apparently occurs only when environmental conditions are optimal and does not occur every year. Only a portion of the total population is involved in this minor spawn; however, the “fall spawn” appears to be important to the maintenance of the commercial stocks into the spring and summer months.

The individual scallop normally reproduces for the first time at an approximate age of either 6–12 months depending upon season of birth and the presence or absence of a fall spawn. Age, however, appears to be less important than environmental conditions since calico scallops as young as 3 months occasionally spawn. Whether or not there are any differences in the viability of larvae produced by scallops of different ages has not been examined. A scallop will normally spawn either 2 or 3 times during its 18–24 month life span, although the number of scallops reaching a third spawn is usually very low.

Like the bay scallop (Sastry 1968; Blake and Sastry 1979; Barber and Blake 1985; Barber and Blake 1991), the environmental controls for reproduction in the calico scallop include food, temperature, and age (Moyer 1997). The current dynamics in the region of Cape Canaveral may also be important to the maintenance of the population and these variables have received considerable study (Lee and Brooks 1979; Leming 1979; Blanton et al. 1981; Lee and Atkinson 1983). During the summer months, coastal upwelling brings deep Gulf Stream water onto the shelf resulting in lowered bottom temperatures. This nutrient rich, colder water may be important in allowing the scallops to accumulate nutrients rapidly.

Miller et al. (1981) have suggested that the cold water intrusions may have both favourable and unfavourable results. On the favourable side, the intrusion may initiate spawning, provide food through phytoplankton blooms resulting from nutrient-rich water, and provide an optimal temperature range of 15–27°C for survival. The intrusions may be unfavourable if bottom temperatures are lowered below 15°C where mortality may occur.

Growth rates are not constant but vary as environmental conditions change (Blake and Moyer 1991; Moyer 1997). Growth rates of greater than 1.5 mm per week can occur during upwelling events and can drop to 0.3–0.8 mm per week as bottom water temperatures increase.

Costello et al. (1973) estimated that calico scallops are planktonic for 16 days under laboratory conditions and set at about 0.25 mm shell height. Therefore, Allen (1979) estimated that 10 mm scallops would be about 51 days old and 28 mm in about 3 months. Considering a two-month interval from spawning to 23 mm, a total of 8 months are required for the scallops to reach 38–40 mm, the commercial size desired by the industry (Blake and Moyer 1991). This period could of course be increased or decreased depending upon environmental conditions, particularly bottom water temperatures.

The calico scallop lives a maximum of two years (Roe et al. 1971). However, since post-spawning mortality may be high, only a small percentage of a year class may survive after 18 to 20 months. Roe et al. (1971) estimated monthly mortality rates ranging from 1% to 31% depending upon the age composition of the population. High mortalities may also occur, even in the young of the population, if bottom water temperatures decrease below 15°C (Miller et al. 1981).

In late 1988 and again in 1991, an ascetosporean parasite, *Marteilia* sp., virtually eliminated the calico scallop population in the vicinity of Cape Canaveral (Moyer et al. 1993). The parasite had not been previously reported in the western Atlantic and the calico scallop population has not rebounded to pre-parasite levels.

17.2.2.3 Fishery

The calico scallop, *Argopecten gibbus*, supports a highly variable fishery (Fig. 17.3) off the coast of Florida and North Carolina. Although the exact locations of commercial stocks vary from year to year, the Cape Lookout, Cape Canaveral, and Cape San Blas areas (Fig. 17.4) are particularly important to the fishery. The North Carolina fishery is small (Table 17.4) and extremely transient (Allen and Costello 1972) but the scallop meats produced are often large for the species and are good quality. The Cape San Blas fishery of Florida is also highly variable and commercial fishing efforts may occur only every 2–3 years and only after other stocks have been depleted.

Figure 17.4. Commercial fishing grounds for the calico scallop, *Argopecten gibbus* (after Blake and Moyer 1991).

* 1991, 1992 and 1993 values for Florida are from the Florida Marine Research Institute, Fishery Dependent Monitoring Program.

The most significant and persistent commercial stock occurs in the vicinity of Cape Canaveral, Florida. Commercial stocks of calico scallops were first observed off Cape Canaveral in 1960 (Bullis and Cummins 1961). Investigations by the Bureau of Commercial Fisheries (now the National Marine Fisheries Service) from 1960 to 1968 showed that commercial concentrations varied greatly along the coast from the St. Johns River near the Florida/Georgia boarder to Fort Pierce, Florida in depths of 19 to 74 m (Bullis and Cummins 1961; Drummond 1969; Cummins 1971; Roe et al. 1971). More

recently the most productive beds have been found to be located in 30 to 50 m of water extending from about St. Augustine, Florida to Fort Pierce, Florida, making a harvestable area of about 2,000 square miles (Fig. 17.4).

The calico scallop grows to less than 3 inches and the adductor muscle (meat) is small and white to pink in colour (meat count range 100–300; normally 150–200). Hand-shucking is not economically feasible; thus, even though large stocks of the calicos scallops were known as early as 1949, the species was not harvested commercially prior to automation in the late 1960's.

Although the current commercial fishery began in 1967, significant landings did not begin until 1980 (Fig. 17.3). This was due to an increase in stocks and to the refinement of automated steam processing equipment. The equipment allowed shellstock representing up to 800 gallons of shucked meats to be processed and packaged within an hour.

Calico scallops are fished using a modified Gulf shrimp trawler. Typically a scallop net, similar to a shrimp net, is towed from each side of the boat. Towing time is regulated and the nets must be equipped with "turtle exclusion devices". No culling occurs and unless processing occurs at sea, the entire catch is returned to shore.

Processing begins as the shellstock is removed from the boat deck by a "knuckle boom". The scallops are then placed in a "batching hopper" which relays the unsorted load to an automated shaker. The shaker removes the broken and dead shell, sand, and unwanted species. Steam is then used to "shock" the scallop meats and to separate the meat and other tissue from the shell. A series of rollers then eviscerates the scallops separating the visceral mass from the adductor muscle. The visceral mass, commonly eaten in other countries, is discarded while the adductor muscle is rapidly cooled in a series of water baths and chill tanks. Quality control includes "hand culling" of any shell fragments or other imperfections before entry into the final series of chill tanks prior to packaging. With the exception of the "hand culling" the entire process can occur without the meats touching human hands and since the product is shipped immediately to a wholesaler or retailer, it can reach the consumer within 24 to 48 hours without being frozen.

The volatile nature of production of this species is clearly demonstrated in Table 17.4 and Fig. 17.3. During the peak in 1984, landings were almost 43 million pounds and reduced to 39,000 pounds in 1991. Annual variations in production of calico scallops impact not only the total catch in the U.S., they also determine the position of the U.S. among other world scallop producers. Landings of calico scallops were 3,572,000 pounds of meats valued at \$US 3,411,000 in 1999. This represented an increase of 1,175,000 pounds (33%) and \$US 1,346,000 (65%) compared with 1998. All calico scallops were landed in Florida in 1998 and 1999. The average ex-vessel price was \$0.86 per pound of meats in 1998 compared to \$0.95 in 1999 (Florida Marine Research Institute, Fishery Dependent Monitoring Program, pers. comm.).

Since stocks of *A. gibbus* are annual, over-fishing has not been considered a problem; thus, there are no state or federal fishery management programs. The fishery is totally dependent upon the natural population and regulation of landings has been attempted by the industry. Fishing efforts are limited until at least 75% of the stock at a particular

location reaches a shell height of at least 38 mm, the point at which much of the population will have undergone their first spawning event. A second spawning is not guaranteed and only takes place when environmental conditions are optimal. Concerns by regulators about the quantity and disposition of by-catch may eventually lead to more formal regulations.

17.3 AQUACULTURE AND ENHANCEMENT

During the years between 1920 and 1926, William Firth Wells carried out some bivalve culture investigations, which he reported in his annual reports to the New York State Conservation Commission. His reports show that besides propagating the eastern oyster, *Crassostrea virginica*, he also cultured quahogs, *Mercenaria mercenaria*, soft clams, *Mya arenaria*, mussels, *Mytilus edulis* and bay scallops, *Argopecten irradians* (State of New York Conservation Department 1969). Wells used a milk separator to clarify his culture water and to collect larvae from cultures for transfer. One of the earliest species he was able to culture was the bay scallop. This was perhaps the first bivalve cultured in the manner similar to what we think of today as aquaculture in the United States (personal communication, Joseph Glancy, now deceased). Most scallop culture in the United States currently utilises the bay scallop, *A. irradians irradians* or *A. irradians concentricus*. No attempts have been made to culture *Argopecten gibbus* in the United States because of its small size and the relatively large natural populations.

The high market value of bay scallops combined with rapid growth and short life span of the species has led to the development and refinement of hatchery, nursery, and grow-out techniques (Castagna and Duggan 1971; Castagna 1975; Rhodes and Widman 1980; Mann and Taylor 1981; Karney 1991; Oesterling and DuPaul 1993; Lu and Blake 1997). Using the information about the natural reproductive cycle investigators have used either artificial conditioning and various stimuli to spawn adults for larval production in a hatchery or relied upon the harvest of reproductively mature adults from the natural environment for spawning stock.

Embryonic and larval stages of marine invertebrates are often the most sensitive to the environmental conditions and extreme mortality of the embryos and larvae can occur if a strict environment is not maintained in a hatchery. Temperature, salinity, and food supply appear to be the most important environmental variables regulating the growth and reproduction of the adults as well as the survival and growth of the embryos and larvae. The combined effects of temperature and salinity on the development of embryos and survival and growth of the larvae of the northern bay scallop, *A. irradians irradians*, was extensively studied by Tettelbach and Rhodes (1981). Only embryos cultured at 20°C–25‰ and 25°C–25‰ showed a greater than 70% normal development. At salinities greater than or lesser than 25‰, normal development declined markedly. Larval survival of this northern subspecies for 2–5 days after fertilisation occurred over a much wider temperature-salinity range with the optimal combination being 18.7°C and 28.1‰. Maximal larval survival at time of settlement occurred at 20°C–25‰. Lu (1996) has shown that this same temperature and salinity combination is optimum for the Florida bay scallop larvae and juveniles and that maximum growth of Florida bay scallop larvae and

juveniles occurs when a food supply of *Isochrysis galbana* is maintained at a density of 10–40 thousand cells per mL of culture.

A number of different techniques have been used in hatcheries to maintain larvae and early juveniles. These techniques have included static, aerated water tanks (Castagna and Duggan 1971; Castagna 1975; Karney 1991; Oesterling and DuPaul 1993; Lu and Blake 1996) for early larval development. Sieves suspended in down-flowing aerated conicals (Karney 1991), raceways or troughs fitted with inserts (Oesterling and DuPaul 1993), and plastic strips suspended in aerated tanks (Lu and Blake 1996) have been used for pediveliger and post-set animals. Flow-through upwelling systems (Oesterling and DuPaul 1993) and nylon-meshed bags suspended in the natural environment (Lu and Blake 1997) are two of the more commonly employed techniques for the nursery of early juveniles from 1–8 mm.

For grow-out, Castagna and Duggan (1971) used large pens in order to demonstrate that a market-sized scallop could be attained in 5–7 months. Early releases of juvenile scallops into the natural environment for commercial harvest proved unsuccessful due to heavy predation (Morgan et al. 1980). Rhodes and Widman (1980) utilised Japanese pearl nets and lantern nets to determine the optimum scallop density for maximum growth in Long Island Sound. Oesterling and DuPaul (1993) used polyethylene trays or plastic mesh cages placed directly on the bottom, placed on cinder blocks, or suspended in the water column on a rack system to demonstrate an optimum density of about 500–800 scallops per square meter for attaining a market-size scallop of 40 mm in 7 months. More recently Oesterling (pers. comm.) employed a floating pen system to suspend the plastic cages in the water column.

Heavy mortalities can occur at all three points in the aquaculture process. Pathogens associated with scallop diseases have been reviewed by Leibovitz et al. (1984). Pathogenic *Pseudomonas* can bloom on the solid surfaces of culture vessels and kill larvae or early juveniles but can be minimised with regular cleaning and water changes (Karney 1991). In the nursery and grow-out stages fouling of the nets or cages can reduce flow rates which leads to reduced growth and increased mortality but this can also be minimised with frequent cleaning (Karney 1991). In the final stages of grow-out, especially during the summer, mortality can occur for unknown reasons (Oesterling, pers. comm.; Lu and Blake 1997) although fouling of the shells by tunicates, barnacles and oysters may be one of the primary causes but frequent cleaning of the shells to decrease the degree of fouling may also lead to mortality.

A number of companies have attempted to culture scallops but have been unsuccessful economically and there is currently no profitable, private aquaculture industry for bay scallops in the United States. Some recent attempts to market the whole bay scallop product to a speciality market have had mixed success due largely to production problems.

The best success with the aquaculture of the species has been in China (Ximing et al. 1999) where in 1982, 26 individuals of *Argopecten irradians irradians* transplanted from the United States were spawned successfully (Fusui Zhang, pers. comm.). Using techniques largely developed in the U.S., the annual bay scallop production in China steadily increased to over 50,000 tons live weight in 1988. The shucked muscles are

imported into the U.S. at \$2.00 per pound (Zhang 1995). This success can be partially attributed to the low cost of abundant labour as well as to the legal utilisation of the total marine habitat.

A few organisations have been involved in enhancement programs, also utilising bay scallops. Perhaps the most successful program of shellfish enhancement is carried out by the Martha's Vineyard Shellfish Group. This is a consortium of 5 towns (Chilmark, Gay Head, Oak Bluffs, Tisbury and West Tisbury) on the island of Martha's Vineyard off the coast of Massachusetts. This group, using a number of federal and state grants, built a solar-assisted hatchery to produce bay scallops, *A. irradians irradians* and clams, *Mercenaria mercenaria* (Karney 1978). The hatchery methods used at Martha's Vineyard are fairly standard except that the seawater is partially warmed in a passive solar system within the solarium-type building. The post-set scallops are held in an indoor, semi-closed nursery system supplemented with cultured algae until the juveniles are 3–5 mm height, then moved out to a small embayment in burlap bags with a brick anchor and a plastic cola bottle inside the bag for a float. Several hundred to a few thousand seed are placed in each bag, which is then anchored over the submerged vegetation found in the bay. This allows the seed to grow to a size that offers sanctuary from some predators before the bag rots away allowing the juveniles to escape a few at a time and spread into the vegetation (Karney, pers. comm.). Each township has legal jurisdiction over its own shellfish waters, sale of harvesting licenses and control of the harvest. Each township supporting the hatchery buys seed at about cost for replenishment or enhancement of an area. The effect of scallop enhancement has been to add a degree of stability to the harvest in the area that is seeded (Karney 1978).

Another enhancement program was carried out in the Long Island Sound area after heavy mortalities of native scallops were observed (see above). The mortality and subsequent recruitment failure was caused by a form of picoplankton, *Aureococcus anophagefferens*. Extensive reseedling of hatchery-reared scallops was initiated in the Peconic Bays by the Long Island Green Seal Committee in 1986 (see Tettelbach and Wenczel 1993). In the following two years, seed scallops (*A. irradians*) were purchased from a number of hatcheries and released in selected areas to enhance or replace the natural populations, which were lost. The effects of this enhancement effort were not quantified in all areas, but a number of scientists involved in this experiment initially believed the effects of the seed planting were minimal (Bricelj et al. 1987; Tettelbach and Wenczel 1993). Recent work by Krause, however, showed about 25% of the scallops in the area were survivors of those released (Krause 1992). Subsequent reseedling efforts were further hampered by the presence of a shell-boring parasite, *Polydora* sp. and yet another "brown tide". While the enhancement efforts are encouraging, the status of the New York bay scallop fishery is still precarious.

Over 100,000 adult bay scallops were transplanted to western Bogue Sound, North Carolina in each of three successive years (1992, 1993, and 1994). Recruitment density at experimental sites increased by as much as 568% while adult densities after recruitment increased by as much as 258%. Recruitment appeared to limit population size in Bogue Sound which implied that larval subsidy through increased spawning stock may enhance bay scallops in the system (Peterson et al. 1996).

In 1996, the state of Florida began an enhancement program along the west coast of Florida from Tampa Bay to Crystal River. Scallops reared in a hatchery and nursery to about 20 mm in size were placed at selected locations in wire cages at a density of 300 per square meter. The growth and mortality of these were followed until spawning. Fouling and mortality of the scallops were severe in the late summer but spawning of the survivors is thought to have contributed to an increased population in the Crystal River area.

17.4 FUTURE

Bay scallops in the eastern United States have historically been considered a delicacy, especially in the local markets where the fresh product is consumed. Its high demand in these markets guarantees a continued high value. However, problems associated with the fishery will need to be addressed.

In addition to showing sharp natural seasonal and annual fluctuations in stock densities, bay scallops along the east coast of North America will continue to be influenced by other pressures that will limit harvests. Loss of habitat through the decline of seagrass beds and the degradation of habitat through algal blooms such as “brown tide” may contribute to the further decline of bay scallop stocks. Also the increase in the public awareness about the occurrence of “harmful algal blooms” may also lead to a decline in the consumption of bay scallops. These problems may eventually lead to the profitability of bay scallop aquaculture, especially if the whole-scallop market develops further. However, the success of bay scallop aquaculture will also be influenced by stringent, governmental leasing regulations, grow-out problems such as fouling, and market development.

The annual landings of the calico scallop fishery will probably continue at relatively low levels (7–10 million pounds) compared to 1984. Although the calico scallop has less value than the bay scallop, the continued landings will ensure its place in the scallop market. It is unlikely that demand for the product will lead to aquaculture ventures in North America.

Chapter 18

Scallops of the West Coast of North America

Raymond B. Lauzier and Neil F. Bourne

18.1 INTRODUCTION

The west coast of North America, defined here as extending from the Mexico-California border to coastal Alaska and into the Bering Sea (Fig. 18.1), is an extensive area that appears to have considerable habitat suitable to support large scallop populations. Although much of the coastal area is mountainous and considerable parts of the coast fall to deep depths within a few km of shore, there are extensive areas with water depths less than 100 m that appear to have good scallop habitat. However, scallop landings from this area have never been large and in 1997 were only 3,181 t, less than 0.2% of world landings for that year (Anonymous 1999).

Although scallop landings from commercial fisheries have been minor, the west coast of North America has a rich scallop fauna. A recent publication (Coan et al. 2000) divided the Suborder Pectinoidea into two Superfamilies, Pectinoidea and Anomoidea (Fig. 18.2). The superfamily Pectinoidea has four living families world wide, two of which, Family Pectinidae and Family Propeasmussidae are well represented along the west coast of North America. Thirteen species of the Family Propeasmussidae have been found in this area, but all are small and most are rare and have a local distribution in deep water. Fifteen species of the Family Pectinidae occur in this area and seven have been or are currently utilised in commercial fisheries: weathervane, *Patinopecten caurinus*, Japanese weathervane, *Mizuhopecten yessoensis*, rock, *Crassadoma gigantea*, reddish or pink, *Chlamys rubida*, and spiny, *Chlamys hastata* (Starr and McCrae 1983; Bourne 1991; Sizemore and Palensky 1993; Shirley and Kruse 1995; Shumway and Castagna 1995; Lauzier and Parker 1999). The Pacific calico scallop, *Argopecten ventricosus*, was harvested in southern California but has been protected since 1954 (Bourne 1991). Minor landings of the Bering scallop, *Chlamys behringiana* (= *pseudoislandica*) were reported from Alaska in 1991 and 1993 (Shirley and Kruse 1995). The other species may be taken in recreational fisheries or for souvenirs but landings are minor.

The absence of sizeable scallop populations is real since numerous surveys have been undertaken to investigate scallop resources in these waters (Quayle 1961, 1963; Rathjen and Rivers 1964; Haynes and Powell 1968; Ronholt and Hitz 1968; Bourne 1969). Other surveys investigated invertebrate resources off the west coast of North America (Grau 1959; Bernard et al. 1967, 1968, 1970). In addition thousands of tows have been made with otter trawls and other dragging gear throughout the area by both research and commercial vessels. No large unknown or unexploited beds of scallops are believed to exist in this area.

Figure 18.1. Map of the northeast Pacific showing the location of some places mentioned in the text.

Although the fisheries are small they are important to local economies and biological studies have been undertaken on several species to develop management policies for fisheries. Further, some species can be readily cultured and initial studies show potential for establishment of a significant aquaculture industry in the area.

Figure 18.2. Scallop species found in coastal waters off the west coast of North America. After Coan et al. (2000).

18.2 FISHERIES

18.2.1 Weathervane Scallop

The weathervane scallop (*Patinopecten caurinus*) provides the largest scallop landings on the west coast and is the species generally referred to when people enquire about the feasibility of establishing a large scallop fishery in the area (Table 18.1).

18.2.1.1 Biology

Weathervane scallops are large and can attain a shell height of 250 mm (Hennick 1973). The lower right valve is larger and more convex than the left and the external colour is yellowish-white to light brown. There are 18–22 squarish flat-topped ribs that radiate from the umbo to the ventral margin. The upper left valve is pale brown to brick red in colour and has 18–22 low and gently rounded ribs. Interior surfaces of both valves

Table 18.1

Landings of scallops in tonnes (whole weight) from the west coast of North America 1967–1999. Unless noted otherwise, landings from Oregon, Washington and Alaska are weathervane scallops, *Patinopecten caurinus*; landings from British Columbia are pink and spiny scallops *Chlamys rubida* and *C. hastata*.

* Includes 1.4 t and 0.3 t of weathervane scallops in 1984 and 1985, respectively.

Tr = Trace, under 1 t

are smooth and glossy white (Coan et al. 2000).

Weathervane scallops are found from central California (37°N) to the northern part of the Gulf of Alaska (60° N), west in the Aleutian Islands to Adlai Island (53°N 174°W) and into the Bering Sea on Petrel Bank in depths of 10–300 m, generally on sand or mud bottom (Grau 1959; Bernard 1983; Kaiser 1986; Shirley and Kruse 1995; Foster 1997; Coan et al. 2000). Distribution is patchy throughout the range and no extensive beds occur; e.g., in British Columbia (B.C.) the two largest centres of population (both relatively small) are in the Gulf Islands region in the southern part of the Strait of Georgia and in Dixon Entrance off the north coast of the Queen Charlotte Islands with small local populations reported from a few other locations. In areas where commercial fisheries occur, distribution is sporadic and local (Starr and McCrae 1983; Kaiser 1986; Shirley and Kruse 1995). In Alaska the fishery occurs on many small beds scattered throughout the vast coastal waters of the southern part of the State but mainly in the Yakutat, Kodiak Island and Dutch Harbour areas (Shirley and Kruse 1995; Kruse et al. 2000). Maximum abundance off Oregon was in 80–100 m and in 70–100 m in Alaska (Starr and McCrae 1983; Kaiser 1986; Shirley and Kruse 1995).

It is interesting that although B.C. is in the centre of distribution of weathervane scallops, only minor populations occur there. The reason for this lack of extensive populations is unknown. It may be due to environmental conditions, excessive predation or perhaps diseases (Bower et al. 1999).

Sexes are separate although a single occurrence of hermaphroditism was reported (Hennick 1971). Sexual maturity is attained at a shell height of 70 mm and spawning occurs at various times. Off Oregon, spawning extended from mid January through June (Robinson and Breese 1984). In the Gulf Islands population of southern B.C., gonads began to fill out in late autumn and by January, it was possible to sex individuals macroscopically by colour. By early April, the gonads were full and spawning occurred from late April to mid June (MacDonald and Bourne 1987). In Alaska, gonads developed from October to May and a single spawning occurred from early June to mid July (Hennick 1970).

Larval development was studied in the laboratory. At 14°C, larvae reached maturity, 250–270 µm, in 28–32 days. Large mortalities were experienced at metamorphosis and few juveniles were raised in the laboratory (Bourne, unpublished data).

Age and growth have been determined for several weathervane scallop populations along the west coast. In B.C., significant differences were observed in growth of populations in the Strait of Georgia and off the west coast of Vancouver Island (MacDonald and Bourne 1987). Mean shell height at annuli and asymptotic shell heights were greater for inshore scallops where they attained a shell height of 100 mm in three years compared to five years in the offshore population. This difference in growth rate was probably due to differences in environmental conditions between the two locations. Another factor causing the difference in growth may be that offshore scallops were generally riddled with sponges and annelids that may cause a diversion of energy for growth to shell repair (Haynes and Hitz 1971; MacDonald and Bourne 1987).

Off Oregon, differences in growth were reported for two populations, one required almost five years to attain a shell height of 100 mm and the other six years (Starr and McCrae 1983). Scallops off Oregon also tended to be riddled with invasive organisms.

In Alaska, growth was found to vary among areas but the asymptotic shell height was similar to that for inshore populations in B.C. (Kaiser 1986; Shirley and Kruse 1995). Scallops attained a shell height of 100 mm in less than two years around Kodiak and in about five years in the Cape Fairweather to Cape Yakutat area.

Weathervane scallops are reasonably long lived. In the Strait of Georgia, animals that measured 230 mm shell height were over 20 years old. In Alaska, a scallop that measured 250 mm shell height was 28 years of age (Hennick 1973).

Few studies have been undertaken to assess causes of mortality in weathervane scallops. Kruse (1994) estimated the instantaneous natural mortality (M) of weathervane scallops was between 0.04 and 0.25, corresponding to annual mortality rates of 4–22%.

Recruitment has been assessed only briefly along the coast. In Oregon, one or two strong years classes supported the brief intense fishery that began in 1981, but since then recruitment has been low. In B.C. and Alaska, recruitment appears to be consistent but low. One indication of low recruitment in B.C. is that size distribution in the Gulf Islands population has varied little over years of sampling with no indication of strong year classes (Bourne, unpublished data).

Limited assessments have been made of populations along the coast (Bourne 1991). A study in Alaska calculated scallop biomass ranged from 12,335 t to 17,445 t in the Cape Spencer-Cape St. Elias area (Ronholt et al. 1977) but this estimate should be regarded as minimal since inefficient gear was used in the survey (Kaiser 1986). Studies are currently underway in Alaska to attempt estimation of scallop populations there (Kruse et al. 2000). Estimates of the small population in the Gulf Islands area of southern B.C. from both dragging operations and observations from the underwater submersible PISCES showed the density was about 1 scallop per 63 square meters (Bourne, unpublished MS).

Size frequency distribution in most populations shows a skew towards larger animals. When liners were used in drags, few small scallops (under 100 mm shell height) were caught. Off Oregon, most scallops caught in surveys were under 130 mm shell height. At two sites, most were between 100–130 mm shell height but at another location most were under 100 mm. Larger animals tended to occur in shallower waters (Starr and McCrae 1983). In Alaska, scallops were considerably larger than reported off Oregon and in commercial samples, most were over 120 mm shell height (Kaiser 1986). The age composition of scallops from commercial catches from 1968 through 1972 showed most were 7–11 years in age in 1968–1970 catches but scallops 2–6 and 7–11 years in age were about equal in 1971 and 1972 samples, indicating the effect of the fishery (Hennick 1973; Shirley and Kruse 1995). In B.C., in spite of using a variety of sampling gear, most animals harvested in the Gulf Islands area have been over 125 mm shell height.

An interesting phenomenon of weathervane scallops occurs in B.C. on the Masset beaches located on the northeast coast of Graham Island in the Queen Charlotte Islands. Generally each winter, live adult weathervane scallops are washed ashore and stranded on these beaches after severe storms. Such strandings may occur three to four times during some winters. Numbers washed ashore may amount to several thousand and they are

collected by residents for local consumption (R. Schatz, pers. comm.). The reason for these strandings is unknown. Several scallop surveys in these waters have failed to locate any significant populations (Bourne 1969).

18.2.1.2 Fishery

Minor landings of weathervane scallops occurred sporadically along the coast until the late 1950's. The only recorded landings for this period were from Washington and between 1936–1952, they averaged about 360 t (Cheney and Mumford 1986).

Explorations in the 1960's led to development of a commercial fishery in Alaska that began in 1967 and has continued to the present (Kaiser 1986; Kruse and Shirley 1994; Shirley and Kruse 1995; Foster 1997; Kruse et al. 2000). Landings have fluctuated for several reasons from a peak of 7,132 t (whole weight) in 1969 to nil in 1978 (Table 18.1). After 1980 they began to increase again and reached another peak of 6,714 t in 1992 but have stabilised at about 3,000 t after 1996 because of management policies (Kruse et al. 2000) (Table 18.1). The number of boats in the fishery has fluctuated from a high of 19 to nil, from 1979 to 1993 they ranged from 1–18 (Kaiser 1986; Shirley and Kruse 1995). Size of boats in the fishery has varied from a keel length of 18 m to over 31, most are between 24–38 m. In recent years, scalloping has become the sole source of income for many of the vessels.

Hennick (1970) described three main fishing areas in the early years of the Alaskan fishery: 1) eastern Gulf of Alaska between Cape Spencer and Cape St. Elias; 2) west side of Kodiak and Afognak Islands and the Shelikof Strait including mainland areas of the Alaska Peninsula; 3) east side of Kodiak and Afognak Islands including Albatross and Portlock Banks. These areas have continued to be important harvesting areas for the fishery, but as the fishery expanded in the 1980's, scallopers explored and exploited new scallop grounds. Landings began and have continued in the Dutch Harbour area, and harvesting began in the Bering Sea in 1986 and extended as far west as Amlia Island along the Aleutian Islands chain. In 1992, scallops were harvested from Prince William Sound for the first time (Shirley and Kruse 1995; Kruse et al. 2000).

In B.C., only minor harvesting has occurred on two small populations in Dixon Entrance and in the Gulf Islands area of the Strait of Georgia. Peak landings were 1.4 t in 1984 (Table 18.1) (Farlinger and Bates 1985).

In Washington, a sporadic fishery has continued on beds located in the coastal area where landings have ranged from a peak of 142 t in 1984 to 0 (Table 18.2) (R.E. Sizemore, pers. comm.). This small sporadic fishery will probably continue and depend on the size of the stocks, economics of harvesting and success in other fisheries.

In the local intense fishery off Oregon, landings peaked at 7,645 t in 1981 and 1,430 t in 1984, but then declined (Table 18.1) (Starr and McCrae 1983). Small landings have continued in a sporadic fishery that depends partly on size of populations and interest in the fishery (Robinson 1997; R. Hannah, pers. comm.).

A small one or two boat fishery harvested weathervane scallops in northern California in 1981 that was an extension of the intense Oregon fishery (Bourne 1991).

Table 18.2

Annual landings (tonnes) and effort in the pink and spiny scallop fishery in British Columbia, 1982–1998, as reported on harvest logs.

* In 2000 both Dive and Trawl commercial fisheries were discontinued and converted to experimental status; 2001 and 2002 are Preliminary Data. # Landings not reported due to confidentiality requirements.

Limited populations of weathervane scallops have been found off Pelican Bay but they are too small to support commercial harvesting.

In the Alaskan fishery, the catch is shucked at sea, adductor muscles bagged and sold when the vessel lands. Attempts were made to use mechanical shuckers but they are now prohibited in the fishery (Shirley and Kruse 1995; Kruse et al. 2000). Most of the catch in the Oregon fishery was shucked at sea but some catches of whole scallops were landed, particularly by smaller boats and shucking was done at shore facilities.

18.2.1.3 Gear

Several types of gear have been used to harvest weathervane scallops on the west coast. Prior to development of fisheries in the 1960's, most of the gear was made locally and frequently old shrimp trawls were used. With development of the Alaskan fishery, most of the gear used was the typical east coast offshore drag (Bourne 1964). Initially many of vessels in the fishery were east coast scallopers that went to Alaska because of the depressed fishing conditions on the east coast (Kaiser 1986). Some Alaskan boats converted to scallopers. The fishery off Oregon was started by east coast scallopers on their way to Alaska (Starr and McCrae 1983; Robinson 1997). Some local boats converted to offshore scallopers and used east coast type drags but other boats, particularly smaller ones, used a variety of gear including shrimp trawls (Starr and McCrae 1983).

18.2.1.4 Management

Several policies have been established to manage weathervane scallop fisheries, the most extensive are in Alaska where the major fishery occurs.

Shirley and Kruse (1995) and Kruse et al. (2000) have described management of the weathervane scallop fishery in Alaska in detail. In the initial stages of the fishery, management was by a set of passive regulations that included gear restriction, type of gear, minimum inside diameter of rings on drags, closed areas to protect crab resources and fishing seasons. With resurgence of the fishery in the 1990's, there was a shift to a more active management of the fishery and the policy now includes number and size of drags, minimum inside diameter of rings (10.2 cm), establishment of nine registration areas with established harvest limits, an overall limit on landings of 4,700 t (whole weight) (1.24 million lbs. shucked meats), area closures to protect crab habitat, limited entry, limit on crew size to 12, ban on automatic shucking machines and establishment of an onboard observer plan to collect data and monitor incidental catches.

When the commercial fishery was open in B.C., weathervane scallops could only be caught with dragging gear with a maximum width of 2 m and a size limit of 120 mm shell height is also in place. Under new management policies, if large quantities of weathervane scallops were found off the B.C. coast it would be classed as a new and developing fishery and biological information would have to be gathered before a commercial fishery was permitted (Perry et al. 1999).

In Washington, the commercial fisheries are regulated by gear size and mesh or ring size. Harvest is also regulated by the tribal rights treaty agreement.

In Oregon, the scallop fishery is regulated by limited entry, a permit system, type of gear and mesh or ring size.

18.2.2 Rock Scallop

Rock scallops (*Crassadoma gigantea*) are unique to the Pacific coast of North America and have an interesting life history.

18.2.2.1 Biology

Rock scallops are large and massive and can attain a shell height of 250 mm (Bourne 1969; Coan et al. 2000). The valves are irregular in shape. In younger animals, the external surface of the upper left valve is sculptured with strong unequal radiating ribs studded with short spines. The valves become massive and are brown or green in colour and are frequently pitted with holes of invasive organisms or encrusted by plant and animal growth. Internally the shell is smooth and white except for the deep purple colour at the hinge area.

An interesting feature of rock scallops is that until they are 2–3 cm in shell height they are free swimming. Auricles on the upper left valve are unequal, the scallop has a roundish appearance and the valves are usually orange in colour. When 2–3 in cm shell height they attach to a rock or other hard substrate by the lower right valve and remain there for life, hence the name purple-hinge rock scallop or rock oyster. In laboratory and hatchery studies, it was found that a small percentage of juveniles ($\approx 10\%$) did not attach to a substrate but remained unattached on the bottom of tanks.

Rock scallops occur from Mexico to the Aleutian Islands in Alaska, Lat. 25–60° N, from the lower intertidal zone (1 m intertidal) to subtidal depths of 80 m (Grau 1959; Bernard 1983; Coan et al. 2000). They occur mostly on subtidal cliffs in areas with strong currents or oceanic surges. Distribution is patchy and they are not particularly abundant in any one locality. No attempts have been made to estimate population size or structure in any area. Generally, there is a preponderance of older animals in most areas.

Rock scallops cannot be aged by measuring annual rings, since the valves become so massive that rings are obliterated. Estimates of age and growth have been made by counting rings on the resilium and from observations in culture work (Leighton 1979; MacDonald and Bourne 1989; MacDonald et al. 1991). In California, *C. gigantea* attained a shell height of 120 mm in two years (Leighton 1979). In B.C., rock scallops in natural populations attained a shell height of 100 mm in about 5 years but a shell height of 90–100 mm, mean 80 mm in three years when grown in suspended culture (MacDonald and Bourne 1989; MacDonald et al. 1991). Rock scallops of 27 years of age were recorded in B.C.

Sexes of rock scallops are separate although one individual hermaphrodite was reported in California (Jacobsen 1977).

Breeding was studied in California and in Puget Sound, Washington. In southern California spawning occurred over a protracted period in two populations (Jacobsen 1977). Both populations spawned from October to January, one population spawned again from March to June and the other from June to August. In Puget Sound, rock scallops spawned from June to August (Lauren 1982). Observations in B.C. indicated that rock scallops have a protracted spawning period from June to October although there may be one or two pulses during this period. The gonad never completely emptied and animals could be sexed macroscopically by colour throughout the year. In experimental work in B.C., rock scallops from wild populations were injected with serotonin biweekly to stimulate spawning, and viable eggs and sperm were obtained from June to January (Bourne, unpublished data).

Larval development has been studied in the laboratory during culture work and also in commercial hatcheries (Cary 1982; Bourne et al. 1989; Agoni, pers. comm.). Larvae reached a mature size of 220 μm in 18–20 days at 21°C.

Observations of populations along the coast indicate that recruitment is probably low but consistent; however, spatfall may be heavier than indicated by recruitment. Quantities of juvenile rock scallops have been collected on oyster strings grown in suspended culture in B.C. and elsewhere. In attempts to collect scallop spat on the west coast of Vancouver Island, about 25% of the collected juveniles were rock scallops, the remainder were pink and spiny scallops, *Chlamys rubida* and *C. hastata* (Bourne 1988; Bourne et al. 1989). Whether sufficient quantities of juvenile rock scallops could be collected consistently along the coast to support large-scale culture operations is not known.

18.2.2.2 Fishery

Attempts were made by scuba divers to harvest rock scallops commercially but they failed because it was too difficult and costly to chisel them off rocks. At present, there is no commercial fishery for rock scallops along the west coast.

Minor landings (less than 1 t annually) reported from California are from aquaculture operations (Shaw 1997; R. Hulbrock, pers. comm.).

Rock scallops are harvested in recreational fisheries along the coast and the catch is regulated by daily harvest limits.

18.2.3 Pink and Spiny Scallops

Two *Chlamys* species, pink scallops and spiny scallops occur widely with overlapping distributions, on the west coast of North America. Fisheries for these two species occur mainly in the inside waters of Washington and B.C.

18.2.3.1 Biology

The pink scallop, *Chlamys rubida* (Hinds, 1845), also known as the smooth pink scallop, reddish scallop, and the swimming scallop (Harbo 1997), was once considered to be a subspecies of *C. islandica* (Waller 1991). A number of subspecies have been named for Asiatic populations; however, they do not appear to have any morphological features that are outside the range of variation for eastern Pacific populations (Waller 1991).

The spiny scallop, *C. hastata* is also known as the pink scallop, Pacific pink scallop, and the swimming scallop (Harbo 1997). There are number of subspecies; *C. hastata hastata*, which ranges furthest south; and *C. hastata hericia* and *C. hastata pugetensis*, which are the two more northerly subspecies (Waller 1991). Here, all are considered as *C. hastata*.

Grau (1959) and Coan et al. (2000) give detailed descriptions of both species. Left valves of pink scallops have 20–42 finely imbricated primary ribs, interspaced with one or more strongly imbricated riblets and reticulated microsculpture. The large anterior auricle has 5 to 12 imbricated radial riblets. The right valve has 18–30 broad flat radial ribs,

bifurcating ventrally, interspaced with a few intercalary riblets, and strongly reticulated microsculpture. The medium-size anterior auricle has 5–6 low smooth radial ribs. The right valve is generally white, and the left valve may be red, pink, orange, or rarely white. Maximum shell height is 71 mm.

Left valves of the spiny scallop have 8–20 primary ribs with strong imbricated spines, interspaced with 1–10 coarsely scaled intercalary riblets and fine striose microsculpture. The anterior auricle has many strongly imbricated radial ribs. The right valve has 12–24 rounded primary ribs, similar to the left valve, but with only 3–4 intercalary riblets. The large anterior auricle has 7–10 imbricated radial riblets. The colour is usually pink to yellow, and often streaked. Maximum shell height is 80 mm.

Shells of pink and spiny scallops are usually encrusted with one of two species of symbiotic sponge, *Myxilla incrustans* and *Mycale adherens* (Harbo 1997). Barnacles, 25 to 30 mm in height, are often attached (Grau 1959).

Pink scallops are found from 33°N – 58°N, San Diego, California to Kodiak Island, Alaska (Bernard 1983). It is not common south of Puget Sound, Washington (Harbo 1997). The spiny scallop is found from 33°N – 60°N, San Diego, California to the Gulf of Alaska (Bernard 1983). Both species have a discontinuous distribution throughout their range along the coast, but can occur in small dense beds (Bourne 1991).

Pink and spiny scallops are epibenthic swimming scallops that typically lie with the right (more convex) valve on the bottom. Like many other *Chlamys* species, they can form a byssus throughout their life, and retain the ability to alternate between attached and detached phases, a characteristic of species with a small body size or species that inhabit relatively high current areas (Brand 1991).

Pink scallops are found at depths ranging from 1 to 200 m in water temperatures ranging from 1°C to 17°C (Bernard 1983). Pink scallops are usually found on softer substrates than spiny scallops (Bourne 1991). Ellis (1967) found only pink scallops on soft harbour sediments in the southern Gulf Islands of British Columbia. Grau (1959) reported pink scallops as usually found off rocky shores. Quayle (1963) found pink scallops throughout coastal B.C. on various substrates, predominantly in sandy and mud substrates, but occasionally on gravel and rocky bottoms.

Spiny scallops are found at depths ranging from 2 to 150 m in water temperatures ranging from 0°C to 23°C (Bernard 1983). They usually occur on firm gravel or rocky substrates (Grau 1959; Bourne 1991) and rocky reefs (Harbo 1997) in areas of strong current (Bourne 1991) but have been found on muddy and sand substrates (Ellis 1967; Quayle 1963). Current was found to be a stimulus to larval settlement (Cooke 1986).

Both pink and spiny scallops are dioecious, and display asynchronous seasonal reproductive activity. Their gonads may not completely empty during spawning, so these species can be sexed throughout the year by the colour of the gonads (Bourne and Harbo 1987). Both species mature at 2 years (Bourne and Harbo 1987) and 25–35 mm shell height. Pink scallops spawn twice a year, first in March and again in September or October, spiny scallops spawn once a year in July or August (Macdonald et al. 1991). In pink scallops, reproductive effort slowly increases with age to an asymptotic maximum that does not exceed its somatic production, but in spiny scallops, reproductive effort increases sharply after three years and exceeds somatic production in its fifth year

(Macdonald et al. 1991). This pattern of increasing reproductive effort is characteristic of most iteroparous pectinids.

Settlement of spiny scallop larvae occurred in 34 days in 16°C water and 42 days in 12°C water (Cooke 1986; Hodgson and Burke 1988). Settlement and metamorphosis was only seen on fouled surfaces. A flow of water also enhanced settlement and metamorphosis.

Growth of both pink and spiny scallops was determined for animals collected from commercial catches (Bourne and Harbo 1987) and during experimental fisheries (Lauzier et al. In Prep). Spiny scallops attain a shell height of 60 mm in 3½ years, pink scallops in 5 years. MacDonald et al. (1991) showed differences in growth and reproductive strategies between pink and spiny scallops. Until recently, the maximum age for both species was thought to be 6 years (Macdonald et al. 1991). However, a small number of individuals (~1%) in biological samples collected from harvested populations in southern B.C. waters were aged at 7, 8 and 9 years (Lauzier, unpubl. data). Preliminary estimates of population size or structure, recruitment, natural and fishing mortality have been undertaken in the first two years of experimental fisheries on pink and spiny scallops (Lauzier et al. In Prep).

18.2.3.2 Fisheries

A small experimental fishery has existed in Washington since 1990 (Sizemore and Palensky 1993) (Table 18.1). There was a sharp decline in landings after 1996 due to large decrease in effort. The fishery is confined to a few vessels certified by the Washington State Department of Health operating in restricted areas and subject to weekly PSP (paralytic shellfish poisoning) monitoring. This fishery is managed by Department of Health actions on PSP monitoring and closures. The fishery is closed annually between July 1 and October 1 due to consistently elevated PSP levels during this period. This fishery is limited by PSP closures rather than stock abundance (R.E. Sizemore, pers. comm.).

Pink and spiny scallops have been commercially harvested in B.C. from 1982 to December 1999 and from 2000 to date under experimental licence. The fishery was confined to inshore waters using two different harvest techniques: a dive fishery and a trawl fishery. Total scallop landings in B.C. from both the dive fishery and the trawl fishery from 1982 to 2002 are shown in Fig. 18.3 and Table 18.2; landings for 2001 and 2002 are preliminary. Landings in the dive fishery comprise 86.8% of the cumulative commercial and experimental scallop fisheries to date. There was a decline in number of vessels as well as vessel days in the trawl fishery in the early to mid 1990's, and a concurrent increase in effort in the dive fishery (Fig. 18.3, Table 18.2).

During the commercial fishery prior to 1999, there was very little available information on the status of pink and spiny scallop stocks in B.C., the only available data were from reported effort and landings. However, fluctuations in effort and landings may have been due to the lack of markets and PSP closures. Pink and spiny scallops are marketed whole, either fresh or frozen. Harvesters claim that limited markets have impeded development of this fishery in the past. Some areas were closed to the fishery

Figure 18.3. Total pink and spiny scallop landings by fishery (trawl and dive) from British Columbia waters, 1982–1999.

because of concerns based on anecdotal information. Experimental fisheries and fishery-independent surveys were implemented in 2000 to provide sufficient information for scientifically-based assessments.

The trawls used in the fishery have evolved since 1990 to produce a marketable product, which is competitive with that in the dive fishery, and to reduce bycatch. The trawls, consisting of a steel or aluminium frame on runners fitted with a rope mesh net bag 2 m wide by 1.4 m deep, were designed to capture scallops as they are swimming, since the crossbar and the bottom of the trawl net is usually 20 cm off the bottom. Only one trawl with a maximum 2 m width is permitted per boat. One particular model, the butterfly scallop trawl, is most commonly used in the trawl fishery. Tests conducted during the experimental fisheries program show considerable variation in butterfly scallop trawl efficiency, but there is virtually no bycatch, and negligible habitat damage.

The trawl fishery occurs generally in depths that are greater than diveable depths, where pink scallops occur more commonly. There is also no size selectivity in the trawl fishery, especially as the trawl bag begins to fill, resulting in a higher proportion of smaller pink scallops in the trawl fishery, as compared to catches in the dive fishery.

Most of the catch in the dive fishery is spiny scallops. Analysis of samples from the dive fishery showed that 81–99% of the catch was spiny scallops, showing divers target on this species. Pink scallops typically occur deeper than the spiny scallops, generally

beyond the diveable depths. Divers in the dive fishery select for larger scallops because of higher economic return.

18.2.3.3 Management

Pink and spiny scallops were passively managed as one species, one stock in B.C. with unlimited entry, minimum size limits (55 mm shell height) as well as seasonal and area closures. Evidence indicates that this management policy was insufficient to sustain stocks in heavily harvested areas. Effort in the B.C. scallop fishery was largely market driven and limited by PSP closures. As markets developed it was felt that a more active management policy was needed to allow for orderly and sustainable development of the resource. Data limited fisheries, e.g., the pink and scallop fisheries, are now considered to be new and developing fisheries, and a process has been initiated, which includes an extensive review of existing information, followed by a framework for experimental fisheries in order to collect additional information identified as missing but necessary for ongoing assessments and a biologically based management policy (Perry et al. 1999).

After an initial review, it was concluded the overall status of pink and spiny scallops in B.C. was unknown, as there was insufficient data for assessment (Lauzier and Parker 1999) and the commercial scallop fisheries were closed on December 31, 1999. Information gaps identified through this review included the distribution of pink and spiny scallop stocks, estimates of biomass, availability of suitable stocks to the fishery, recruitment, natural and total fishing mortality.

B.C. pink and spiny scallop fisheries are now considered as experimental fisheries (Perry et al. 1999). A framework for assessment and management of B.C. pink and spiny scallop fisheries was prepared and approved that included identification and delineation of scallop assessment and management units, along with a systematic plan of biomass surveys (Lauzier et al. 2000). Experimental fisheries and biomass surveys that collect biological samples to assess age structure, growth and natural mortality have been undertaken since 2000 in collaboration with the dive and trawl fleets. There is also an ongoing re-evaluation of minimum shell height and its applicability to each species. The present plans include progressing towards limited dive and trawl commercial fisheries, with continued regular biomass surveys and biological data collection for scientifically based assessment programs and management plans.

18.3 AQUACULTURE

Scallop populations along the west coast of North America are limited. No large unknown harvestable beds are believed to exist in the area and hence future landings from fisheries will remain similar to those at present. Current management policies are designed to maintain these levels of landings. Occasional dense sets of weathervane scallops may occur in some areas that could support periodic intense local fisheries as occurred in Oregon (Starr and McCrae 1983) but this would be infrequent. If scallop landings are to increase significantly on the Pacific coast they will have to result from development of scallop aquaculture operations.

There is considerable interest in scallop culture along the west coast for several reasons, among others; the emerging acceptance of aquaculture as a reliable method to increase aquatic production, the long success of the oyster industry and recent development of Manila clam, *Venerupis philippinarum*, culture in the area, strong markets for scallops, but above all the outstanding success of scallop culture in Japan (Ventilla 1989; Aoyama 1989; Ito 1991) and more recently in China (Guo et al. 1999). Scallop production from Japan and China is entirely from culture operations and accounts for about 90% of present world landings. The west coast has considerable areas of protected waters and the belief is they could support extensive scallop culture operations.

Initial attempts have been made to investigate the feasibility of scallop culture in several areas along the west coast and a small industry exists at present (Bourne and Bunting 1995). In any culture operation a primary requisite is an abundant, reliable and inexpensive supply of juveniles (seed). Much of the scallop culture research along the west coast has focused on developing methods to provide this consistent supply of seed. Juveniles for culture operations can be obtained in two ways; from natural sets, or from production in hatcheries. There are advantages and disadvantages to both methods. The large culture operation in Japan obtains its entire supply of juveniles from natural sets (Ventilla 1982). Where large consistent natural sets do not occur, juveniles must be produced in hatcheries but this can add significantly to costs of culture operations.

18.3.1 Pink and Spiny Scallops

Attempts were made by research workers and industry in Washington and B.C. to culture pink and spiny scallops (Bourne 1991). An advantage of pink and spiny scallop culture is that seed can be collected from natural sets, up to 2,000 juveniles per collector bag. Species composition of sets was not determined although it was believed most of the sets were spiny scallops. Some sets had rock scallops and at one site approximately 25% of the set was rock scallops. A problem in using juveniles from natural sets could be separating species.

The conclusion from culture studies with pink and spiny scallops was they are too small and growth is too slow (MacDonald et al. 1991) to support an economically viable culture operation. No further work was done with either species other than perhaps as a hobby farm operation.

Another problem with pink and spiny scallop culture is that as mentioned previously, the whole scallop is marketed. Outbreaks of shellfish toxins could cause periodic closures of pink and spiny scallop culture operations (Shumway and Cembella 1993).

18.3.2 Weathervane Scallop

The weathervane scallop appears to be an ideal candidate for culture on the west coast. It is native, large, has a rapid growth rate and it should be possible to produce commercial sized animals (100 mm shell height) within a period of 2–3 years. Experimental work was undertaken in Washington, B.C. and Alaska to investigate the potential for weathervane scallop culture.

Attempts to collect juveniles from natural sets in all three areas failed. In Washington, no juveniles were caught. In B.C. only 10 were collected in one year and none in two other years, probably because of heavy sets of the crab, *Cancer oregonensis* in the collector bags. In Alaska, a joint project between the State of Alaska and the Japanese Overseas Fishery Cooperation Foundation (OFCF) attempted to collect juvenile weathervane scallops but few were caught. The conclusion from this work was that no areas are known along the coast where large quantities of juvenile weathervane scallops can be caught consistently to support a large culture operation as occurs in Japan.

Since juvenile weathervane scallops cannot be obtained from natural sets the alternative is to produce them in hatcheries. Work was undertaken in Washington (Olsen 1983; 1984) and in B.C. by both research workers and industry to develop methods to breed weathervane scallops (Bourne et al. 1989; R. Saunders, pers. comm.). The species has proven extremely difficult to breed successfully in labs or hatcheries and few juveniles were produced, too few to use to develop nursery methods or to use in extensive growout trials. Research studies are needed to solve the bottleneck of producing large quantities of weathervane scallop seed consistently in hatcheries before the species can be considered for culture operations along the coast. At present, there is no current work on weathervane scallop culture on the west coast.

Weathervane scallops were crossed with Japanese weathervane scallops to determine if such a hybrid had advantages for culture in B.C. The cross was successful and DNA testing was undertaken and continues to show this is a successful cross. Breeding of this cross has continued and offspring are used in culture operations in B.C. (R. Saunders, pers. comm.).

18.3.3 Rock Scallops

There was considerable interest in rock scallop culture in California, Washington and B.C. in the 1970's and early 1980's resulting from work in California where methods were developed to produce juveniles in hatcheries and grow them to commercial size in the open environment (Leighton and Phleger 1977; Phleger and Leighton 1980; Phleger et al. 1981; Cary 1982; Phleger and Cary 1983). Results showed it was possible to culture rock scallops to a shell height of 100 mm in two years in California.

Experimental rock scallop breeding was undertaken in Washington (Olsen 1983, 1984) and in B.C. and methods were developed to breed rock scallops and grow them to commercial size (Bourne et al. 1989). In B.C., growth was reasonable and a shell height of 80 mm was attained in three years (MacDonald et al. 1991). Rock scallops have an advantage over other species in that as mentioned above, juveniles attach themselves to a substrate and remain there the rest of their lives. In culture operations, juveniles were attached to a variety of substrates, growth was good and mortalities were low; however, a problem was experienced in growout. Rock scallops tend to assume the shape of the substrate they are attached to and frequently were thin, hence the adductor muscle was also thin. Several substrates were investigated as a surface for attachment but none was widely accepted. Interest in rock scallop culture generally declined.

Recently there has been renewed interest in rock scallop culture along the Pacific coast. Small production has occurred in California incidental to an oyster culture operation (Shaw 1997) and limited harvest was made by divers from offshore oil rigs (C. Culver, R. Hulbrook, pers. comm.). The possibility of using offshore platforms for rock scallop culture is being investigated. Experimental breeding of rock scallops has also occurred in Oregon (A. Robinson, pers. comm.).

In Washington, limited rock scallop culture was undertaken by one company incidental to oyster culture operations; methods were developed to breed rock scallops in a hatchery and grow them to commercial size (J. Agosti, pers. comm.). Annual production was small, under 1 t, but rock scallops from this operation were on the menu of a restaurant in Seattle in March 2000 (Bourne, pers. obs.). Recently another company has initiated a project to produce seed in their hatchery and attempt growout in exposed areas of the coast (J. Davis, pers. comm.).

Significant developments have occurred in rock scallop culture in Alaska (J. Agosti, pers. comm.). Seed is now produced routinely in a hatchery and there are at least three farms licensed to grow and sell rock scallops in the southeast part of the state and more are expected to begin culture operations. It is expected that by the end of 2000 there will be several farms culturing rock scallops in the state. Rock scallop culture could become a significant industry in the state in the next ten to twenty years.

Rock scallop culture has considerable potential along the west coast of North America. The bottleneck of a consistent seed supply has been solved with production from hatcheries. The problem will be to develop nursery and growout systems to permit economically viable production of deeply cupped marketable size rock scallops. However, with continued research and development it is expected this can be achieved in the near future permitting development of a significant rock scallop industry.

18.3.4 Japanese Weathervane Scallop

In 1981, a research project was initiated to determine the economic feasibility of scallop culture in B.C. Initial work focussed on four native species, weathervane, rock, pink and spiny but none proved to be a suitable species. A decision was made to import the Japanese weathervane scallops (*Mizuhopecten yessoensis*) and determine if it could be cultured in B.C. Considerable biological information existed on this species, broodstock was available and a large culture industry existed in Japan (Ventilla 1982). Broodstock was imported under quarantine conditions and methods were developed to breed them in a hatchery, culture juveniles in a nursery and grow juveniles to commercial size. The species proved to be a suitable candidate for culture in B.C.; seed could be readily produced in a hatchery and they could be grown to commercial size (100 mm shell height) at various locations in B.C. within two years (Bourne et al. 1989; Bourne and Hodgson 1991).

Commercial scallop culture began in B.C. in 1989 with construction of a hatchery by a private company using technology developed in the research program although the company has developed considerable new technology since then. Scallops can be bred routinely over an extended period and large quantities of juveniles produced in a land built

nursery. Production could be easily expanded to meet a much larger demand. Methods have been developed to avoid predation of juveniles by a flat worm, *Pseudostylochus orientalis*, and to avoid high mortalities in growout that occurred at some locations because of a protozoan disease, *Perkinsus gugwadi* (SPX) (Blackbourn et al. 1998; Bower et al. 1998, 1999). Using offspring of the weathervane-Japanese weathervane cross, a strain of Japanese weathervane scallops has been produced that appears to be immune to this disease and mortality rates are greatly reduced. Scallops measuring 100 mm shell height can be produced within a 2 y period at several sites in B.C. Maximum annual production has been about 200 t from a maximum of ten farms (R. Saunders, pers. comm.).

The company has developed other techniques for scallop culture, among them the ability to ship eyed (mature) larvae and juveniles to all parts of the world. They have successfully shipped them to Morocco, where a Japanese weathervane scallop industry is beginning. Eyed larvae and juveniles have also been successfully shipped to Japan.

The future of scallop culture in B.C. continues to be bright but continued improvements are needed in all phases of culture to make scallop farming more economically attractive. It is estimated that annual production of juveniles will need to be about 40 million to make the hatchery-nursery complex economically viable. To some extent it is a problem of critical mass that requires a sufficient number of people to become involved in scallop culture to make operations of a scallop hatchery economically viable. Scallop culture has been proven in B.C. and the industry must now develop to a sufficient level to attract investment to achieve its potential.

18.3.5 Pacific Calico Scallop

Mention should be made of a Pacific calico scallop, *Argopecten ventricosus*, culture operation. A Washington State company has initiated a project to rejuvenate a scallop culture industry in Baja California, Mexico, using the Pacific calico scallop (Felix-Pico 1991). Some seed may be produced in their Washington hatchery, but it is expected that most if not all operations will be based eventually in Mexico (K. Johnson, pers. comm.).

18.4 FUTURE

Scallop landings from fisheries for natural stocks on the west coast of North America will probably continue at present levels in the foreseeable future. No large unknown populations of any harvestable species are believed to exist in the area that could add significantly to landings and management policies for pink, spiny and weathervane scallops are in place to assure continued existing sustainable production.

Landings of weathervane scallops will continue to be virtually all from Alaska unless dense year classes settle in other areas, but this will be infrequent. Weathervane scallop resources are now actively managed in Alaska with an annual overall cap of 4,600 t that will maintain landings at or below this level. If occasional dense populations are found in other areas, management policies are in place to assure optimum utilisation of the resource.

Landings of pink and spiny scallops are expected to remain low, about 200–300 t annually and will be mostly from B.C. and Washington. A problem in this fishery could be outbreaks of shellfish toxins that appear to be increasing in frequency in recent years. Since the entire soft parts of these species are consumed, such outbreaks could lead to more frequent closures in these fisheries. Another limiting factor in this fishery in B.C. has been market development. Harvesters claim that limited markets have impeded development of this fishery in the past. However, as markets develop and strengthen, there is a need for biologically-based assessment and management systems that allow for orderly and sustainable development of the resource. Resource inventory surveys are being conducted for B.C. pink and spiny scallop stocks, as a first step towards structured stock assessments and an active management system.

Scallop production on the west coast of North America could increase in the future through aquaculture.

There is little, if any, potential for culture of pink and spiny scallops and considerable research and development is required to solve the problem of a large, consistent supply of weathervane scallop seed for culture operations. If juvenile weathervane scallops can be produced at reasonable cost then the species could have potential for culture on the west coast.

A small industry culturing Japanese weathervane scallops exists at present in B.C. that could be greatly expanded. Large quantities of seed can now be produced consistently in a hatchery. The efficiency of all phases of culture need to be improved and strong support is needed from governments to involve more people in scallop culture and make it an economically attractive business. It is expected that production in this culture industry will continue to increase in the future.

There has been a resurgence of interest in rock scallop culture along the entire west coast and the seed supply problem has been solved, at least to some degree, with production from hatcheries. Continuing research and development is required to improve the efficiency of culture operations to make rock scallop culture an economically viable industry. Results of such studies could result in establishment of a rock scallop culture industry on the west coast in the near future.

ACKNOWLEDGMENTS

Many people have aided us in preparation of this paper. In particular we would like to thank the following people for sharing information and data on scallops with us; J. Agosti, J. Barnhart, B. Bunting, C. Carver, J. Davis, R. Hannah, R. Hulbroch, K. Johnson, G. H. Kruse, A. Robinson, R. Saunders, R. Schatz, and R. E. Sizemore.

Chapter 19

**The European Scallop Fisheries for *Pecten maximus*,
Aequipecten opercularis and *Mimachlamys varia***

Andrew R. Brand

19.1 INTRODUCTION

Although 28 species of scallop have been recorded in European waters (Nordsieck 1969), relatively few are of large enough body size and occur in sufficiently dense concentrations to be commercially exploited. Of these, the 'great scallop', 'coquille Saint-Jacques' or simply 'scallop', *Pecten maximus* (L.) is the most important on account of its wide distribution and high market value. In recent years, the common name 'king scallop' has also been applied to this species, a name introduced by the U.K. industry to distinguish it from the second most important species, the 'queen scallop', 'queen' or 'queenie', *Aequipecten* (formerly *Chlamys*) *opercularis* (L.). The Iceland scallop, *Chlamys islandica* (Müller) is also of considerable economic importance, but is a sub-arctic species and has a more restricted European distribution. Finally, several other species are of more limited local importance including the 'St. James' or 'pilgrim's scallop', *Pecten jacobaeus* (L.), which replaces *P. maximus* in most of the Mediterranean, the 'black' or 'variegated scallop', *Mimachlamys varia* (L.), and the 'smooth scallop', *Flexopecten glaber* (L.).

Pecten maximus and *A. opercularis* both have a long history of exploitation and in recent years have been the subjects of important commercial fisheries by boats from England, Wales, Scotland, Northern Ireland, the Republic of Ireland, the Isle of Man, the Channel Islands, France and Spain. These fisheries, and the stocks that support them, have been occasionally investigated by ICES Working Groups (Anonymous 1979, 1989) and other workers. Mason (1983) reviewed the history of the fisheries around the British Isles and gave a general account of the catching, processing and marketing of these species, and there have been more specific studies of the fisheries of England and Wales (Franklin et al. 1980a), Northern Ireland (Briggs 1980a; Briggs 1987), the Isle of Man (Brand et al. 1991a; Brand and Prudden 1997; Brand 2000) and Guernsey (Jory 2000). Scallop fisheries in France have been described by Dupouy (1978), Dupouy et al. (1983) and Dao and Carval (1999), and in Spain by Cano and Garcia (1985) and Román (1991). More limited information is also available for various pectinid fisheries in Italy (Renzoni 1991; Mattei and Pellizzato 1996), Yugoslavia (Margus 1990; Margus 1991) and Greece (Lykakis and Kalathakis 1991). There is a very extensive literature on the biology and ecology of *P. maximus* and *A. opercularis*, but that for *M. varia* is more limited. Previous work on these three species has been reviewed by Mason (1983) and more recently by

Ansell et al. (1991). This section aims to bring the latter work up-to-date by incorporating studies on the biology of these three species that have come out over the last ten years and presenting, where possible, the latest information on their fisheries. Although *C. islandica* is a commercially important European scallop species, it is not included in this section, nor is any information given on the Scandinavian fisheries for *P. maximus* or *A. opercularis*, as these topics are covered elsewhere in this volume.

Pecten maximus and *Aequipecten opercularis* have similar geographical ranges along the east coast of the North Atlantic from northern Norway to West Africa, the Azores, Canary Islands and Madeira (Tebble 1966; Mason 1983; Brand 1991) but *A. opercularis* extends farther into the Mediterranean and the Adriatic (Broom 1976; Cano and Garcia 1985; Piccinetti et al. 1986). They are found from just below the low water mark to a depth of more than 150 m (Forbes and Hanley 1853; Tebble 1966) but are essentially coastal species, most common at 20–45 m. *P. maximus* occurs on bottoms of clean firm sand, fine gravel or sandy gravel, sometimes with an admixture of mud; *A. opercularis* is frequently found on the same grounds but it can also live on harder gravel and shelly bottoms (Mason 1983). *P. maximus* is predominantly an Atlantic species but it does extend along the south-eastern coast of Spain into the Mediterranean and a bed off Malaga has been commercially fished since 1982 (Cano and Garcia 1985). It has long been considered that *P. maximus* is replaced throughout most of the Mediterranean by the morphologically distinct *P. jacobaeus*. A number of genetic studies using allozyme electrophoresis (Huelvan 1985), mitochondrial DNA (Wilding et al. 1999) and partial sequences of the 16S rRNA gene (Canapa et al. 2000) have suggested that the genetic distance between *P. maximus* and *P. jacobaeus* is too small to consider them as separate species. However, the recent studies by Ríos et al. (1999, 2002), based on allozyme frequencies, found a major genetic discontinuity in the area of the Almeria-Oran oceanographic front that was coincident with the morphological discontinuity between the two taxa and appears to confirm the specific status. The main areas of commercial exploitation of *P. maximus* and *A. opercularis* are along the western coasts of the British Isles and France, but include the Moray Firth off the north-east coast of Scotland, the Shetland Islands and both sides of the English Channel (Brand 1991).

The smaller *Mimachlamys varia* does not extend quite as far north as the other two species but it has a wide distribution from Denmark, along the western coasts of the British Isles, France and the Iberian peninsula, throughout most of the Mediterranean and as far south as Senegal on the coast of west Africa (Tebble 1966). Light (1988) considers that *Mimachlamys nivea* is a geographical sub-species of *M. varia*, confined to the west coast of Scotland. *M. varia* occurs at depths ranging from the low intertidal to some 80 m, usually on shelly or sandy-gravel sediments where it byssally-attaches to shells, stones and boulders (Le Pennec and Diss-Mengus 1985) or rock faces (Rodhouse and Burnell 1979). It is also often a prominent member of the epifauna on banks of the horse mussel, *Modiolus modiolus* (Jones 1951). The main commercial exploitation of *M. varia* is along the French Atlantic coast, in recent years particularly the eastern part of the Bay of Brest.

19.2 BIOLOGY AND ECOLOGY

19.2.1 The Great Scallop, *Pecten maximus* (L.)

Pecten maximus is a large scallop. In many areas it can grow to a shell length (the largest dimension) of 150 mm but some even larger individuals have been recorded, including one with a shell length of 210 mm (Minchin 1978). It is inequivalve, with a flat upper (morphological left) valve and a deeply cupped lower (right) valve that generally overlaps the left at its margin. Both valves bear 15–17 broad, radiating ribs and numerous concentric corrugations and fine striae. The left valve is generally reddish brown in colour but can vary from light pink to almost black. The right valve is usually off-white, yellowish or light brown. Both valves can be marked with bands, spots or zigzags of red, pink or bright yellow. Growth rings are often very clear on both valves, particularly the left.

P. maximus is usually found recessed into shallow depressions in the seabed so that the upper valve is level with, or just below, the surface of the sediment (Baird 1958). Recessing is a complex, closely coordinated, behaviour pattern involving powerful jetting of water from the mantle cavity. The entire process usually takes from 2–20 minutes to complete, but depends on the nature of the sediment (Maguire et al. 1999), and scallops as small as 6–10 mm recess (Minchin 1992; Minchin et al. 2000). Particles of sand disturbed by the water jets resettle on the shell so that recessed scallops are difficult for visual predators or divers to detect. On settling from the plankton, and for some time after, juvenile scallops are byssally-attached but they can release the byssus to move to a new location where they secrete a new byssus. Scallops cease to form a byssus at a small size and few larger than 15 mm are attached (Eggleston 1962; Franklin et al. 1980a; Minchin 1992).

Whether recessed or byssally-attached, young scallops swim readily when disturbed. Like most pectinids, *P. maximus* appears to have three responses to disturbance (Thomas and Gruffydd 1971; Brand 1991): closing the valves, a jumping reaction that propels the scallop hinge foremost and a more vigorous swimming reaction that propels the scallop ventral edge foremost. Movement is achieved by powerful water jets from the mantle cavity, generated by shell adductions. Scallops are good swimmers when young but swimming performance and willingness to swim decline with age (Mathers 1976a; Minchin and Mathers 1982; Jenkins and Brand 2001). Jumping and swimming provide an escape reaction from predators, divers and fishing gear. Contact with predatory starfish elicits vigorous escape reactions, whereas non-predatory starfish evoke more minor reactions or none at all (Thomas and Gruffydd 1971; Soemodihardjo 1974). Many of these responses are chemosensory. The ability to discriminate between potential predators and harmless species minimises interruptions to feeding and prevents energy being wasted making unnecessary escape reactions, resecreting the byssus or reconstructing a recess (Thomas and Gruffydd 1971). Reactions to divers or fishing gear involve responses to light, water currents or vibrations (Baird 1958; Minchin and Mathers 1982) and have important implications for commercial fishermen (Chapman et al. 1979). The fast phasic adductor muscles of *P. maximus*, like other scallops, store glycogen as an energy reserve

and contain high levels of adenosine nucleotides and arginine phosphate (Ansell 1977; Grieshaber and Gäde 1977). Swimming adductions are fuelled, at least initially, by the anaerobic metabolism of the arginine phosphate; this is subsequently regenerated aerobically from the resulting octopine when swimming ceases (Gäde et al. 1978; Grieshaber 1978). As a consequence of these physiological mechanisms, scallops are well adapted for short distance escape responses but they become rapidly fatigued and take a long time to recover after swimming (Grieshaber and Gäde 1977; Gäde et al. 1978; de Zwaan et al. 1980). Such characteristics are inappropriate for long-distance swimming and there is no sound evidence, from direct observations or tagging experiments, of *P. maximus* or any other scallop species undergoing extensive, directed migrations (Brand 1991). However, when one scallop swims it often induces swimming in others nearby, leading to mass swimming activity (Minchin and Mathers 1982; Howell and Fraser 1984), and repeated swimming can result in downstream dispersal in areas with strong water currents.

After disturbance, scallops attempt to recess by repeated ejection of water jets directed at the sediment (Baird 1958). Swimming movements may be used to move short distances if the sediment is unsuitable for recessing. The speed of recessing (Maguire et al. 2002) and swimming ability (Jenkins and Brand 2001) are greatly reduced after the stress of dredge capture, so undersized discards may be less able to escape from predators. Once recessed, scallops are less vulnerable to predation, and probably feed more efficiently (Brand 1991). Recessed scallops orientate to water currents so that mantle cavity ventilation is assisted (Hartnoll 1967; Mathers 1976a). This probably increases the efficiency of filter feeding and imposes rhythms of feeding and digestion, phased with the tidal cycle (Mathers 1976b). Living at the interface between sediment and water column, scallops encounter sedimenting phytoplankton, suspended benthic diatoms and resuspended detritus (Christensen and Kannevorf 1985). In a comparative study of the feeding ecology of *P. maximus* and *A. opercularis* in a strongly tidally mixed area of the north Irish Sea, Lawrence (1993) found that resuspended benthic diatoms were present in the benthic boundary layer throughout the year and comprised the major dietary item of both species. Planktonic diatom species were only available, and present in the gut contents, in spring and early summer. She concluded that *P. maximus* probably receive a lower quality diet than *A. opercularis* since they draw in water from nearer the sediment surface and take in more detritus. Laboratory experiments showed that *P. maximus* has higher clearance rates and exhibits greater particle selection than *A. opercularis*, but is more sensitive to resuspended sediment in the diet. Pseudofaeces production occurs at algal concentrations exceeding $10 \text{ cells } \mu\text{L}^{-1}$ so enhanced food levels in the sea do not necessarily increase scallop growth (Skjaeggestad et al. 1999).

Within their geographical range scallops have aggregated distributions at different spatial scales. For various scallop population's scales of aggregation have been defined, with some variation in terminology, by a number of workers (Orensanz 1986; Caddy 1989a; Brand 1991; Orensanz et al. 1991). These range from the largest, which is the 'stock', 'reproductively isolated population' or 'megapopulation', down through the 'fishing ground', the 'bed' and the 'patch'. Since the degree to which the scale of aggregation can be perceived depends on the size of the sampling unit (Andrew and

Mapstone 1987), reliable estimates of scallop density and stock size are difficult to obtain, and the comparison of estimates based on different survey methods is problematic. Stock assessments of *P. maximus*, based on dredging, have been carried out regularly in several areas, particularly around the coasts of Scotland (Mason and Drinkwater 1976; Mason et al. 1980, 1981, 1984), and the north Irish Sea (Murphy 1986; Brand et al. 1991a; Allison 1993; Brand and Allison 1994; Beukers-Stewart et al. 2001a). Scallop density and catch per unit effort (CPUE) show a long-term decline on all Isle of Man fishing grounds, with densities of <0.03 scallops m^{-2} now typical of the inshore fishing grounds and many of the offshore grounds (Brand and Prudden 1997). There is a closed season for scallop fishing throughout the north Irish Sea (June–October inclusive), and for the most heavily exploited fishing grounds, where the populations are dominated by young scallops, there are large seasonal variations in density. Estimates of density of legal-sized scallops (>109 mm shell length) on all the heavily fished grounds are now usually around 0.03 scallop m^{-2} , at the start of the fishing season, a level clearly perceived by fishermen to be economically viable and dependent largely on the strength of summer recruitment (Wilson and Brand 1995). By the end of the season, however, densities have fallen to around 0.01 scallops m^{-2} , which probably approximates to the density that the fishermen currently consider to be uneconomic. When densities fall to this level the fishermen move off and fish elsewhere. These values may be compared with earlier density estimates for the same grounds of 0.09 – 0.12 scallops m^{-2} for 1954/5 and 0.2 for 1965/6 (based on tagging), 0.04 – 0.11 for 1981/4 and 0.03 – 0.04 for 1986/90 (based on dredge CPUE) and 0.01 – 0.03 for 1989/92 (based on diving) (Mason and Colman 1955; Gruffydd 1972; Murphy 1986; Allison 1993; Wilson 1994). The density estimates based on dredge CPUE assumed a dredge efficiency of 20%, a value derived from earlier studies (Chapman et al. 1977; Mason et al. 1979a). However, in a recent study, Beukers-Stewart et al. (2001a) reported rather higher dredge efficiencies for one Irish Sea fishing ground. Using two independent methods of assessment, they calculated ‘Newhaven’ spring-tooth dredge efficiencies for legal sized scallops (>109 mm shell length) of 29.5% from a depletion experiment and 40.7% from a concurrent diver survey of dredge tracks. Other work has shown that the efficiency of spring-tooth dredges varies on different substrates from 6% on stony ground to nearly 40% on smooth grounds (Dare et al. 1993), so some of the densities quoted above are likely to be underestimated, while others are overestimated. An even greater variation in dredge efficiency with substratum type was reported in the study by Buestel et al. (1985), carried out by divers following ‘French’ dredges (with a diving plane) in the Bay of St. Brieuc, France. They found an average density of 0.6 scallops m^{-2} over an area of some 33 km^2 of the bay, with dredge efficiency ranging from 25–74% on different sediments.

The use of diving, dredging and towed television camera surveys to assess the distribution and density of *P. maximus* was compared by Mason et al. (1982). They found that, compared with divers, dredges recovered only 18% of the scallops in their path and 36.3% were observed using underwater video. Diver surveys record the highest numbers of scallops but can only cover a relatively small area and are restricted in the water depth in which the divers can operate effectively. Divers also often select areas with abnormally high local densities, and diver estimates of up to 8 scallops m^{-2} have been recorded

(Minchin and Mathers 1982). Underwater video can survey larger areas, operate in deeper water and give information on large-scale patchiness in scallop distributions (Giguère and Brulotte 1994; Hall-Spencer et al. 1999). Franklin et al. (1980b) used underwater television to survey stocks of *P. maximus* and *A. opercularis* in the English Channel off Devon and Cornwall. While the mean densities over the whole area surveyed were 0.16 scallops m^{-2} and 0.46 queens m^{-2} , they found maximum densities for two-minute videotape segments (approximately 20 m^2) of 2.33 scallops m^{-2} and 4.46 queens m^{-2} . Thouzeau and Hily (1986) developed the A.QUA.R.E.V.E. system that combines a video camera with a dredge and this has been very successful for surveying juvenile scallop abundance (Thouzeau and Lehay 1988). Recently, Hall-Spencer et al. (1999) concluded that video surveys underestimate the density of recessed scallops because they are difficult to discern on the screen. In a survey of *P. jacobaeus* in the Gulf of Venice they recorded an average density of only 0.023 scallops m^{-2} from the videotapes but subsequently caught 0.025–0.034 scallops m^{-2} in the same area using a 'Rapido' trawl for which they had calculated a capture efficiency of 44%.

Growth in *P. maximus* is strongly seasonal and most populations can be easily aged by counting the rings laid down on the shell when growth resumes in spring (Mason 1957). Problems can be encountered with the identification of the first ring, and with the later rings in scallops aged more than 10 years (Mason 1983; Allison 1993). However, validation by repeated seasonal observations of the position of the most recently formed ring in relation to the edge of the shell, tagging and recovery, growth experiments with spat of known ages (Paul 1981; Allison et al. 1994) and oxygen isotope analysis (Dare and Deith 1991) have all shown that this traditional method of ageing *P. maximus* can be cheap, rapid and reliable. In addition to the annual growth rings, the shells of *P. maximus* also bear fine concentric ridges or striae that have been considered to represent daily growth increments (Antoine 1978). Gruffydd (1981) cast doubts on the reliability of this method when he reported that the frequency of formation of striae of juvenile *P. maximus* in good culture conditions was very variable, but always less than one per day. Deviation from a daily deposition of growth rings have been confirmed in all the more recent studies of *P. maximus*, and other scallop species, but various mechanisms have been proposed to account for these deviations and the technique would appear to be very valuable for investigating seasonal and environmental factors affecting growth (Chauvaud et al. 1998; Chauvaud and Strand 1999).

The growth pattern of *P. maximus*, in terms of both shell length and meat weight, generally conforms to the von Bertalanffy growth formula (Broom 1976; Murphy 1986; Allison 1993), but the Gompertz equation may provide a better fit for the younger age classes (Pope and Mason 1980; Mason 1983). Other model-free methods of analysis have also been used (Aldrich and Lawler 1996). Seasonally oscillating growth models that account for the winter cessation of growth have also been fitted (Allison 1994). The latter are of particular value for calculating potential meat yields from the fishery, and investigating exploitation strategies, because the edible portions of pectinids (the adductor muscles and gonads) show such large seasonal cycles. There have been numerous studies of the growth rates of *P. maximus* at different locations around the British Isles and France, and the older studies are reviewed in Mason (1983), Buestel and Laurec (1976)

and Antoine et al. (1979a). Growth rates on different fishing grounds have been compared from growth curves of mean length or weight-for-age (e.g., Mason 1957; Gruffydd 1974a), from the parameters of the von Bertalanffy growth formula (Antoine et al. 1979a; Murphy 1986; Acosta and Román 1994) or from growth performance indices derived from these parameters (Allison 1993). Large differences in growth rate have been found between different populations, both on a wide geographical scale and between relatively closely situated locations, and these differences have been attributed to various environmental and other factors. Acosta and Roman (1994) conclude that, with some exceptions, growth rate is higher, the asymptotic length is smaller, and the life span is shorter in southern populations. In the north Irish Sea, growth rates of scallops are generally highest on the inshore fishing grounds off the west and north-eastern coasts of the Isle of Man and lowest on grounds farther offshore to the south and east of the Island (Allison 1993). Thouzeau and Lehay (1988) also found that the growth of juvenile *P. maximus* was highest at onshore locations in the Bay of St. Brieuc.

Differences in temperature, organic carbon content of the seston and current speeds at the different sites were considered to explain the differences in growth rate of *P. maximus* in suspended culture (Wilson 1987b), and similar factors were suggested to explain growth differences in juvenile scallops in the Bay of St. Brieuc (Thouzeau and Lehay 1988). Chauvaud et al. (1998), however, concluded that normal growth of *P. maximus* is regulated mainly by bottom-water temperature, salinity and, to a lesser extent, river flow, rather than food, but they found that toxic algal blooms led to major reductions in shell growth rate. Laing (2002) found that food cell clearance rates and mean growth rate of *P. maximus* spat were usually significantly lower at a salinity of 28 psu than at 28–30 psu, while Laing (2000) also suggests that temperature rather than food is the factor most often limiting growth in the sea. Food can, however, be a limiting factor in both natural (Gruffydd 1974a) and cultivated (Norman and Minchin 1999; Maguire and Burnell 2001) populations. It would seem that genetic factors play only a minor part in determining shell growth characteristics. Thus, the native growth characteristics were not retained when *P. maximus* spat were transplanted from the Bay of St. Brieuc to the Bay of Brest (Antoine et al. 1979b), or when Irish and Scottish scallops were transplanted to sites in Brittany (Dao et al. 1985a; Huelvan 1985). However, scallops transplanted from Mulroy Bay had significantly lower growth rates and carbohydrate content than native Bantry Bay scallops grown under the same conditions (Maguire and Burnell 2001), so further studies are necessary. Unlike many other bivalves there appears to be no association between heterozygosity and size in either natural populations or hatchery-reared families of *P. maximus* (Beaumont et al. 1985), and this has been confirmed for other pectinids (Fevolden 1992). In *P. jacobaeus*, the level of heterozygosity has been related to the timing of spawning (Ríos et al. 2002).

Size and age distributions of natural populations have been extensively studied for populations around the coasts of Scotland (reviewed in Mason 1983), the Isle of Man (Brand et al. 1991a; Allison 1993; Brand and Prudden 1997; Brand 2000), Northern Ireland (Briggs 1991; Briggs 1995) and France (Dupouy 1978; Dupouy et al. 1983; Lubet et al. 1991). In all fished areas there has been a shift in the population age structure towards the younger age groups as the older and larger scallops are progressively removed

by size-selective fishing. This is particularly evident on the most heavily fished grounds, like the Bradda Head ground off the south west of the Isle of Man, where for the last 15–20 years up to 70% of the catch has been 4 years old or less, and mainly below the minimum legal landing size (110 mm shell length) (Brand et al. 1991b; Brand and Prudden 1997). The success of the fishery on such grounds is very dependent on the strength of annual recruitment. Annual recruitment has been remarkably regular for many years on inshore grounds in the north Irish Sea (Brand et al. 1991a; Beukers-Stewart et al. 2001b), while elsewhere it can be very variable. For example, Dupouy et al. (1983) cited a ratio of 20:1 between good and bad year-classes in the Bay of St. Brieuc. For many larger fishing grounds, recruitment may be temporally regular but with considerable spatial variability (Gruffydd 1974b; Bannister 1986). The strength of annual recruitment can be predicted by pre-recruitment surveys for 1 and 2 year old scallops using small mesh dredges (Thouzeau and Lehay 1988; Thouzeau 1991a; Allison 1993; Palmer 1995; Beukers-Stewart et al. 2001b). Future recruitment of each year-class may also be predicted at an early age from the numbers of spat settling in artificial collectors (Buestel et al. 1979; Fraser 1991; Beukers-Stewart et al. 2001b), particularly for very strong year-classes.

Pecten maximus is a long-lived scallop, with a life span exceeding 20 years in extreme cases (Tang 1941). However, the average life span is much less, even in unexploited populations (Dupouy et al. 1983). In the north Irish Sea the populations on all grounds were dominated by old scallops before fishing began, with up to 50% of the population 9 years old or older (Brand et al. 1991a). By 1995, after 15–50 years of exploitation, the populations on all the inshore grounds and many of the offshore grounds were dominated by young scallops, with up to 70% of the catch less than 4 years old and scallops older than 7 years were rare (Brand and Prudden 1997). There have been relatively few studies of the mortality rates of *P. maximus* in either unexploited or exploited populations. The most detailed estimates have come from two large tagging experiments carried out on the stocks around the Isle of Man (Brand and Murphy 1985; Murphy 1986; Allison et al. 1989; Brand and Murphy 1992; Allison 1993), and from analyses of CPUE and population age structure data (Murphy 1986; Wilson 1994) for the same stocks. Annual exploitation rates from the tagging experiments carried out in 1982/3 and 1987/8 were very high for the inshore grounds, with values of up to 55%, while for some of the offshore grounds exploitation rates increased from 1–5% in 1982/3 to 5–20% in 1987/8 (Brand et al. 1991a). Fishing mortality (F) increased considerably between the 1982/3 and 1983/4 fishing seasons on all grounds and has been maintained in subsequent years. While natural mortality (M) increases with age, F appears to be similar for all recruited age-classes, implying that all fully recruited age-classes are equally vulnerable to fishing. The estimates of natural mortality ($M = 0.31–0.61$) derived from tagging experiments (Brand et al. 1991a) are considerably higher than the assumed value of $M = 0.15$ commonly used in *P. maximus* stock assessments (Mason et al. 1979b; Mason et al. 1981), but these values include incidental or non-capture mortality (F_i) caused by dredge damage. Recent studies have shown there is the potential for high levels of mortality in undersized discards and scallops that encounter the dredges but are not captured (Jenkins and Brand 2001). It is most important that F_i can be separated from M ,

for M is used as a constant in stock assessment models and must not vary with the amount of fishing. Incidental mortality is an important, but often neglected, factor and can considerably exceed M in some other scallop fisheries (e.g., Naidu 1988; Shepard and Auster 1991). An estimate of $M = 0.12$ for one north Irish Sea ground in the absence of fishing (Allison 1993) is similar to the value of 0.164 previously calculated for 7 year old scallops from an un-fished Manx population (Gruffydd 1974b), suggesting that the conventionally assumed value of 0.15 is reasonable for these grounds.

The main predators of *P. maximus* are decapod crustaceans (*Cancer pagurus*, *Carcinus maenas*, *Liocarcinus puber*) and starfish (*Asterias rubens*, *Marthasterias glacialis*), but certain gastropods, octopus and fish can be important in some areas (Minchin 1991; Halary et al. 1994; Lake and McFarlane 1994; Grall et al. 1996; Veale et al. 2000a). The range of potential predators is much greater for spat and juvenile scallops (Brand et al. 1980; Minchin 1984; Fleury et al. 1996), including unexpected predators like the sea anemone *Anthopleura ballii* (Minchin 1983). Predation on *P. maximus* is reduced when the spat leave sites of byssal attachment and start to recess in the seabed (Buestel and Dao 1979). Older scallops appear to have a refuge in size from many predators (Paul et al. 1986; Lake et al. 1987; Lake and McFarlane 1994) but this can sometimes be overcome (Wilson and Brand 1994). The vulnerability of small scallops to predation has important implications for stock enhancement or bottom culture and has been the subject of much research in recent years (e.g., Dao et al. 1985a; Paul et al. 1986; Halary et al. 1994; Lake and McFarlane 1994; Maguire et al. 2002). A survival rate of 75–90% per year was reported for juvenile scallops of greater than 25mm shell height experimentally seeded in the Bay of Brest (Dao et al. 1985a), but scallops up to 60mm or more have been highly vulnerable to predation elsewhere (Paul et al. 1986; Lake et al. 1987; Lake and McFarlane 1994), making site selection, predator removal and control, or enclosure of the scallops in nets, cages or corrals, important for economic success. In addition to predators, periods of prolonged cold weather, like the very cold winter of 1962/3, may also cause mortality of scallops in shallow water populations (Boucher and Fifas 1997). Although blooms of toxic or noxious algae appear to be coming more frequent occurrences in European waters, as elsewhere, and have led to fisheries closures (Andersen 1996; Campbell et al. 2001), they do not generally cause the mortality of adult scallops, though growth and reproduction may be inhibited (Shumway and Cembella 1993). Algal blooms can, however, cause serious mortalities of *P. maximus* larvae and juveniles (Minchin 1984; Lassus and Berthome 1988; Erard-Le Denn et al. 1990; Glemarec 1997).

Diseases do not appear to be a major cause of scallop mortality in the sea. Apart from mass mortalities in the Bay of St. Brieuc, France, in 1985–6, caused by a rickettsiales-like microorganism (RLO) in the gills (Le Gall et al. 1988; Le Gall et al. 1991), there are few records of disease in natural populations of *Pecten maximus*. Mortensen et al. (1992) isolated infectious pancreatic necrotic virus from scallops in Norway but in a later health survey (Mortensen 1993) found no serious pathological agents. Similarly, a recent detailed survey found very few pathogens or parasites in two U.K. scallop populations (Lohrmann 2000). The RLO described by Le Gall (1988) was common in *P. maximus* from the English Channel, with a prevalence of 33.3%, but was completely absent from

Irish Sea samples, although RLOs were present in *Aequipecten opercularis* taken from the same grounds (prevalence 15%), but this was probably a different species. The only parasite found in *P. maximus* from the Irish Sea was a coccidian present in the kidney (prevalence 5.3%) and this was absent from the Channel population. An unusual mass-mortality of *P. maximus* spat in nursery cultivation near Bergen, Norway, was caused by massive settlements of the polychaete *Polydora* sp., which bores into the shell (Mortensen et al. 1999), but it is not known if *Polydora* causes mortalities in natural populations. Under hatchery conditions, bacterial and viral infections of larvae and brood stock remain a serious problem for *P. maximus* culture, but this is considered elsewhere in this volume.

Environmental pollution has only rarely been reported to be a problem for natural populations of *Pecten maximus*, or any other European scallop. Routine monitoring for metals, organochlorine pesticide and PCB residues in the U.K. (e.g., Portmann 1979; Franklin 1987; Franklin and Jones 1995) have shown no cause for concern. Scallops accumulate various metals, often to many times their environmental concentrations (Bryan 1973). Many of these accumulate in the kidney as metal-phosphate granules, prior to excretion into the urinary tract (George et al. 1980). Cadmium is also bound to proteins in the digestive gland, accumulating to a level of approximately 100 ppm wet weight (Stone et al. 1986). The affects of various anti-fouling compounds have been tested on juvenile and adult scallops in cultivation. High levels of copper accumulated in scallop tissue from copper oxide-based anti-fouling paint and especially from copper-nickel alloy trays (Davies and Paul 1986) but there was no significant accumulation of nickel. There was some increase in the growth of spat with the copper oxide treatment, but growth of the adult scallops was not affected; the copper-nickel trays, however, caused high mortalities and inhibited growth in adult scallops (Paul and Davies 1986). Bis-(tri-n-butyltin) oxide (TBT)-based anti-fouling paint was detrimental to the growth and survival of juvenile scallops but had no effect on adult scallops. There was, however, evidence for the operation of a storage/detoxification mechanism in adult scallops that involves the progressive transfer of TBT to the adductor muscle (Davies et al. 1986). There is also evidence that very poor spat settlement and decline of the adult population of scallops in Mulroy Bay, Ireland, in the period 1982–85, was caused by the use of TBT-based anti-fouling net-dips using in salmonid farming (Minchin et al. 1987a; Minchin and Ni Donnachada 1995; Slater 1995). There is very little evidence that environmental pollution from the large European oil and gas exploration and production industry, or tanker spillage, has had much impact on *P. maximus* populations (Grainger et al. 1984). The recent development of a method for maintaining scallop digestive acini alive *in vitro* opens up new possibilities for using *P. maximus* in ecotoxicology research (Le Pennec and Le Pennec 2001).

Pecten maximus is a simultaneous hermaphrodite, with the prominent mature gonad containing a proximal, creamy-coloured testis and a distal, orange-coloured ovary, of approximately equal size. The first detailed work on scallop reproductive cycles was that of Mason (1958a b), who combined descriptions of the histology of the gonad structure with subjective assessments of the stage of development, based on the external appearance of the gonad. This work subsequently became the model on which virtually all studies of seasonal scallop reproduction world-wide were based, although the range of

study techniques subsequently broadened to include various weight-based gonad indices and stereological analyses of cell volume fractions. Mason's study was on scallops from the inshore fishing grounds around the Isle of Man, where adult scallops usually have two peaks of spawning each year: a partial spawning in spring (April or May) and a more complete and closely synchronised spawning in autumn (late August or September). There may also be a minor partial summer spawning in July or early August. Virgin and juvenile scallops differ in having only one major spawning, in autumn. Mason (1958b) also provided evidence of a possible lunar periodicity in spawning, with peaks of spawning at full moons. A similar annual pattern, with two main peaks of spawning each year for adult scallops, has also been reported in other areas, including south-west Ireland, Galway Bay on the west coast of Ireland (Wilson 1987a), Strangford Lough in Northern Ireland (Stanley 1967), Loch Torridon on the west coast of Scotland (Mason 1969) and, with some variation in the extent of the summer recovery, in the Clyde (Comely 1974). Other studies, however, have shown both latitudinal and local variations in the timing and number of annual spawning peaks, and the degree of synchronisation between individuals.

At the northern end of the geographical range, in western Norway, Strand and Nylund (1991) recorded single spawning peaks for two populations, the most northerly having a closely synchronised spawning in June and the more southerly a less well-synchronised spawning in late July-August or August-September. In Loch Creran, on the west coast of Scotland, there is also only one main spawning period each year, but the timing can vary from year to year and spawning is not closely-synchronised between all individuals in the population (Fegan et al. 1985; Mackie 1986). While two main spawning peaks are usual for most Irish Sea populations, Wanninayake (1994) found different seasonal cycles in two closely located populations. The Laxey Bay population in 20–30 m water depth conforms to the usual seasonal pattern for the inshore grounds (Mason 1958a; Duggan 1987; Allison 1993), with distinct spawning peaks in spring or early summer (April–June) and again in autumn (August–September). In contrast, the offshore Port St. Mary population, 30 km farther south and in 50–70 m water depth, has only a single summer peak (June–July). In addition, although summer spawning starts later in the Port St. Mary population, the recovery of the gonads after spawning occurs 1–2 months earlier. Thus full gonads are present for a longer period in the Port St. Mary population, and gonad index and gonad weight are higher for much of the year. In the absence of any late summer or autumn spawning peak, this deeper water Irish Sea population therefore resembles populations farther north in the geographical range.

Populations of *P. maximus* farther south in the geographical range show further variation in seasonal patterns of gametogenesis, spawning and recovery (Lubet et al. 1991). This is particularly apparent for populations in different parts of the English Channel. In the Bay of St. Brieuc, on the northern coast of Brittany, native scallops show highly synchronised maturation of all individuals in spring, leading to a massive spawning in July; this is followed by secondary spawnings until the end of August but, uniquely, recovery of the gonad is then delayed until the following spring, when they mature rapidly (Paulet et al. 1988; Mackie and Ansell 1993). This cycle differs markedly from that in the nearby Bay of Brest, where the scallops show little synchrony between

individuals and there are repeated cycles of maturation of cohorts of gametes throughout the year (Cochard 1985; Paulet et al. 1988). Many of the oocytes produced during the winter months, however, become atretic, undergo cytolysis and are probable resorbed, rather than being spawned (Dorange and Le Pennec 1989; Le Pennec et al. 1991). This results in considerable seasonal variation in the quality of the gametes produced (Cochard 1985; Paulet et al. 1992). There are also differences in the egg size, larval life span and duration of metamorphosis, highlighting differences in reproductive strategy between the two bays (Paulet et al. 1988). Much research on the reproductive cycle has also been carried out on the scallop population in the Bay of Seine (Lubet et al. 1987a, b; Lubet et al. 1991) where the sexual cycle is continuous throughout the year but the spawning season is restricted to the period July–October, and oocyte lysis occurs from November to the following July. The most southerly investigations of *P. maximus* have been for a natural shallow water population (Acosta and Román 1994) and stocks in suspended culture in the Ria de Arousa, NW Spain (Pazos et al. 1995; Pazos et al. 1996; Pazos et al. 1997a). Here, there are two main spawning peaks, one in winter (February–March) and one in late spring and early summer (May–July), but minor spawnings are possible in late summer and early autumn, giving a very long spawning season. Some authors have suggested that the presence of large numbers of atretic oocytes at certain times of the year appears to be characteristic of shallow, warmer water populations towards the southerly end of the geographical range (Ansell et al. 1991; Besnard 1991; Lubet et al. 1991). However, this conclusion was drawn before oocyte lysis had been reported in some of the most northerly (Strand and Nylund 1991), and the most southerly (Pazos et al. 1995), *P. maximus* populations. The adaptive significance of this seemingly energetically wasteful reproductive strategy in some populations – and its apparent absence from populations around Britain – has not been explained, although it has been suggested that oocyte lysis and resorption may provide energy for metabolism when the energy supplies from the adductor muscle and ingested food are insufficient (Lubet et al. 1987c; Strand and Nylund 1991), or to develop new oocyte cohorts (Paulet and Boucher 1991). Lubet et al. (1991) conclude that it is ‘an adaptive response to environmental conditions’. Of these, temperature and food supply are likely to be the most important.

Differences in reproductive strategy are usually closely linked with seasonal cycles of energy acquisition and storage. In scallops, metabolic reserves of protein and glycogen are stored mainly in the adductor muscle, and lipids are stored mainly in the digestive gland. Seasonal cycles of energy storage and utilisation have been studied in various tissues in relation to the spawning cycle for populations of *P. maximus* in Norway (Strohmeier et al. 2000), Scotland (Comely 1974; Mackie 1986), the Irish Sea (Wanninayake 1994), France (Faveris 1987; Lubet et al. 1987b; Faveris and Lubet 1991) and Spain (Acosta and Román 1995; Pazos et al. 1997a, b; Roman et al. 1999). During the seasonal cycle there are periods of net accumulation of reserves, when the protein and glycogen content of the adductor muscle and the lipid content of the digestive gland increase, and periods of net depletion when these reserves are utilised to contribute to metabolic requirements for maintenance, or for the development of the gonad. In Norway, spawning coincides with the spring phytoplankton bloom and switches in

energy allocation appear to divide the year clearly into two parts: priority is given to somatic growth and energy storage in the period from June to October, while reproductive growth occurs only from October to June (Strohmeier et al. 2000). On the west coast of Scotland, metabolic reserves increase through the spring and summer, with only a slight reduction during the main spawning season, to reach a peak in autumn (Comely 1974; Mackie 1986). The reserves in the adductor muscle and digestive gland then decline during the winter, contributing to maintenance and the requirements of the rapidly developing gonad. A very similar cycle of energy storage and utilisation has been reported for scallops in the Ria de Arousa, Spain, the most southern population so far investigated (Pazos et al. 1997b). In Irish Sea populations the seasonal pattern of change is also generally similar, but there is some variation between fishing grounds. Energy reserves build up to higher levels in the deeper water Port St. Mary offshore population and, with no autumn spawning on this ground, the recovery of the gonads and the depletion of stored reserves proceeds 1–3 months earlier than in the shallow water Laxey Bay population (Wanninayake 1994). For both grounds the fall in lipid contents in the digestive gland during the period of gametogenesis, plus a small contribution from the adductor muscle, was more than adequate to account for the lipid increase in the ovary, but specific fatty acids may need to be synthesised from other substrates. In the French populations the seasonal cycles of biochemical reserves are more complex, with significant falls in glycogen and lipid in summer, coinciding with spawning (Faveris and Lubet 1991; Mackie and Ansell 1993). Hence, in Bay of Seine scallops, there are two major peaks in energy reserves, in December and in July (Lubet et al. 1987a, b).

Many of the differences in the reproductive and energy storage cycles that have been reported for different populations of *P. maximus* undoubtedly represent responses to differing environmental conditions, particularly variations in temperature, food supply and day length. However, for other populations, particularly those in the closely located Bays of Brest and St. Brieuc, there is evidence that the differences are determined by genetic factors, acting independently of the environment (Paulet et al. 1988; Mackie and Ansell 1993). This implies the existence of genetically distinct stocks in different localities and hence some degree of genetic isolation between stocks. Strong support for this hypothesis has come from a series of transplant experiments carried out in the Bay of St. Brieuc, by scientists from IFREMER, Centre de Brest, in association with local fishermen's organisations. This work was undertaken as part of a restocking programme that aimed to reinstate commercial stocks in the Bay by introducing juvenile scallops from other localities (Dao et al. 1985a, b). Batches of young scallops were taken from spat collectors near the Isle of Scalpay (Scotland) and hatchery reared spat from the Bay of Brest, and grown alongside native St. Brieuc scallops. The reproductive and storage cycles of the native stocks in these two areas differ in well-defined ways from the native stocks of the Bay of St. Brieuc. Unfortunately, a full reciprocal transplant experiment was not possible because national legislation prohibits transfers of shellfish between some areas. The results, never-the-less, provide very strong evidence that genetic factors control features of the reproductive cycle (Ansell et al. 1988; Mackie and Ansell 1993). Both Scottish and the Bay of Brest transplants retained critical features of their reproductive cycle after growing in the Bay of St. Brieuc for two years. In both these

stocks, recovery of the gonad began in late summer, soon after spawning, and there was no post-spawning refractory period that is so characteristic of St. Brieuc native scallops. As a result, the mean state of maturity of the transplants diverged progressively from that of the St. Brieuc natives, and the reproductive cycle was less well synchronised between individuals. Since the three stocks were growing under identical environmental conditions, the study strongly suggests that some features of the reproductive cycle are under genetic control, and additional evidence to support this has come from hatchery conditioning trials carried out on the same native and transplant stocks (Cochard and Devauchelle 1993). At the same time, other aspects of the reproductive cycle, such as the time and duration of spawning, are clearly subject to environmental influence (Mackie and Ansell 1993). Thus spawning and recovery of the gonads started later, and with a longer spawning period, in Scottish native scallops growing on the west coast of Scotland, than in Scottish transplants in the Bay of St. Brieuc. The seasonal cycles of energy storage and utilisation also appear to be under environmental, rather than genetic, control. There was no detectable difference in the annual pattern of accumulation and utilisation of reserves between the Scottish and Bay of Brest transplants and the native Bay of St. Brieuc stock, growing under the same conditions, despite the different reproductive cycles. Further evidence comes from the experimental studies of Saout et al. (1999a) who found that energy partitioning between somatic growth and gonad growth was strongly influenced by the experimental manipulation of temperature and day length. The relative influence of genetic and environmental factors therefore differs for the reproductive cycle and the storage cycle. This finding is potentially important, for the two cycles might become de-coupled in transplanted populations (Mackie and Ansell 1993) and this could have significant, but unpredictable, biological and commercial consequences.

While the studies of reproductive adaptations from transplant experiments and hatchery conditioning strongly support the existence of genetically distinct stocks, at least for the native scallops from the Bay of St. Brieuc, direct studies of genetic variability, using the techniques of gel electrophoresis, failed to find any genetic differentiation between any of the scallop populations studied (Beaumont et al. 1993). This agreed with earlier studies comparing *P. maximus* populations from Scotland, Ireland and Brittany (Huelvan 1985), and from different grounds around the coast of Scotland (Morvan in (Ansell et al. 1988)). The high values for the mean genetic identity between populations shown in these three studies suggested that the European stocks of *P. maximus* might be a single panmictic unit, in keeping with the relatively long pelagic life of the species. However, genetic differentiation has been detected in similar studies of the queen scallop, *Aequipecten opercularis* (Mathers 1975; Beaumont 1982b; Beaumont and Beveridge 1984; Lewis 1992; Lewis and Thorpe 1994a; Lewis and Thorpe 1994b), which has a very similar geographical distribution and a comparable larval life span (Le Pennec 1982). Since the failure to detect small-scale differentiation between *P. maximus* populations could be a consequence of the limitations of the allozyme methodology, in which only a few loci were available for analysis, some more recent studies have used high-resolution DNA-based methods. Wilding et al. (1997) used PCR-RFLP of mitochondrial DNA to investigate population structure of

P. maximus from the U.K., Ireland and Brittany. They found no evidence of differentiation within and between the U.K. and Brittany populations (including Bay of St. Brieuc scallops), but the population from Mulroy Bay, Ireland, was distinct from the others. This latter finding was confirmed by Heipel et al. (1998), using RAPD (predominantly nuclear DNA) markers. They found significant variation between populations from Mulroy Bay, Plymouth (southwest England) and the Irish Sea. In addition, they reported a low but significant degree of differentiation between five commercially fished grounds around the Isle of Man. A subsequent study of restriction-site variation in two PCR-amplified mitochondrial DNA fragments, carried out on the same samples (Heipel et al. 1999), also showed evidence of population differentiation. Mulroy Bay was again distinct from the other populations, and had the lowest genetic variability of all the sites, reflecting the relative isolation of this very enclosed water body. There was also slight but significant differentiation among the Isle of Man populations, with the East Douglas fishing ground appearing distinct from the other Manx locations. These two papers provide the first evidence of population genetic structuring in exploited open-water stocks of *P. maximus*. Recently, Ridgway and Dahle (2000) have also used restriction analysis of PCR-amplified mtDNA fragments to show that the Norwegian and British scallop populations belong to different gene pools. The identification of genetically relatively isolated stocks in different areas, from studies of reproductive ecology or genetic differentiation, is an essential element in the management of fisheries for it has important implications for stock assessments, stock enhancement and cultivation projects involving the transfer of stocks from one area to another.

When *Pecten maximus* spawns the eggs and sperm are released into the water column where fertilisation takes place. The fertilised egg then develops through the usual trochophore and shelled veliger stages, during which it filter-feeds on phytoplankton, and grows to a length of about 250 µm before settlement and metamorphosis occurs (Le Pennec 1974). There is a large and rapidly growing literature on the development, growth, survival and nutritional requirements of *P. maximus* larvae under hatchery conditions (reviewed elsewhere in this volume) but studies under natural conditions are few. In the sea, the length of larval life depends on environmental factors like temperature and food availability, but genetic factors may also be important (Paulet et al. 1988). The larvae are probably in the plankton for 3–8 weeks before settlement, during which time they are carried with the currents (Le Pennec 1974; Paulet et al. 1988; Beaumont and Barnes 1991). Survival in the planktonic phase is strongly influenced by hydrographic conditions, the availability of food, the abundance of predators and competitors, and the presence of unusual conditions such as toxic algal blooms or local depletions of oxygen (Minchin 1985; Erard-Le Denn et al. 1990).

Natural settlement of scallop larvae is mainly on emergent filamentous substrates such as bryozoans and hydroids that provide an erect, silt-free, surface (Eggleston 1962; Soemodihardjo 1974; Mason 1983; Dare and Bannister 1987; Minchin 1992). After initial settlement, small *P. maximus* spat (250–530 µm shell length) appear to be capable of secondary dispersal by bysso-pelagic drifting (Beaumont and Barnes 1991; Beaumont and Barnes 1992). There is also experimental evidence that quinone or quinone-like

compounds, such as occur in aqueous extracts of certain red algae like *Delesseria sanguinea*, can act as chemical inducers of metamorphosis (Chevolot et al. 1991). Around the Isle of Man most pectinid spat have been found attached to bryozoans of the genus *Cellaria* (Brand et al. 1980) but they will settle on a wide range of natural and artificial surfaces including ropes and plastic netting. This behaviour provides the means of capturing large numbers of naturally produced spat for cultivation (see elsewhere in this volume). Since spat of *P. maximus* is notoriously difficult to find on the seabed, artificial spat collectors provide scientists with a convenient technique to study seasonal and spatial patterns of settlement (Brand et al. 1980; Paul et al. 1981; Wilson 1987c; Fraser 1991; Thouzeau 1991b, c; Zhang 1996; Nance 2001) and a possible means of making early predictions of year-class strength in the commercial fishery (Fraser and Mason 1987; Burnell 1989; Brand and Prudden 1997; Beukers-Stewart et al. 2001b). There is recent evidence that settlement peaks off the west coast of Scotland occur on, or close to, the dates of full moons (Nance 2001). The results of spat collector studies can be difficult to interpret, for in such studies it is often impossible to distinguish between differences in initial settlement and differences in early survival (Zhang 1996). This could account for some of the apparent discrepancies noted between the seasonal pattern of settlement in spat collectors and seasonal patterns of spawning in the local populations shown by studies of gonad maturation stages (Brand et al. 1980; Wilson 1987a), rather than attributing these discrepancies to large-scale larval transport mechanisms. The relationships between gonad maturation, spawning, larval abundance, spat collection and recruitment in the Bay of St. Brieuc were reviewed by Boucher (1985). He concluded that, for this area, the influence of environmental factors such as temperature leads to synchrony of gonad maturation and mass spawning, which is a major determinant of recruitment. Despite numerous other studies in France (Fifas et al. 1990; Thouzeau 1991a; Paulet et al. 1992; Boucher and Fifas 1997; Saout et al. 1999b) and elsewhere (Fraser 1991; Allison 1993; Dare et al. 1994), factors affecting recruitment to commercial stocks remains one of the least well understood aspects of *P. maximus* ecology. While discussing the general problem of scallop recruitment in relation to management, Sinclair et al. (1985) suggested that the main commercially fished grounds of *Pecten maximus*, *Aequipecten (Chlamys) opercularis* and *Placopecten magellanicus* are self-sustaining. Subsequent hydrographic (Darby and Durance 1989; Dare et al. 1994) and genetic (Lewis and Thorpe 1994a; Lewis and Thorpe 1994b; Heipel et al. 1998; Heipel et al. 1999) studies are providing increasing support for this conclusion.

19.2.2 The Queen Scallop, *Aequipecten opercularis* (L.)

The queen scallop *Aequipecten opercularis* is smaller than *Pecten maximus*, growing to a maximum shell height of about 90 mm. The shell is inequivalve but, unlike *P. maximus*, both valves are cupped. The more deeply cupped upper (left) valve can be of a range of colours, including yellow, orange, red, brown and purple; the lower (right) valve is generally lighter in colour, frequently off-white, buff or brown. Both valves can have a conspicuous pattern of lines, spots or other markings in various colours. The shell colour is often much brighter and more variable in the first few months, after which it

frequently becomes orange-brown but the first growth zone retains its original colour, albeit fading throughout life. There are some 19–22 broad radiating ribs on both valves, together with numerous concentric growth striae that aggregate to form growth rings. The visibility of the growth rings varies considerably from ground to ground in this species but they are seldom clear.

As with *Pecten maximus*, the first settled stages of *Aequipecten opercularis* are byssally attached to stones, shells or epibenthic organisms. The morphological characteristics for identifying small spat of *A. opercularis* have been described, together with comparative descriptions of six other pectinids from the western Mediterranean, including *Pecten jacobaeus*, *Mimachlamys varia*, *Flexopecten glaber* and *Flexopecten flexuosus* (Peña et al. 1998). *A. opercularis* spat settles very readily on artificial collectors, so the distribution, abundance and various aspects of the early biology of queens have been frequently studied (e.g., Brand et al. 1980; Paul 1981; Brand et al. 1991b; Thouzeau 1991b, c; Chauvand et al. 1996; Román et al. 1996; Zhang 1996; Nance 2001). Queen scallops retain the ability to attach until quite a large size, although the proportion that is byssally-attached falls with age and most queens larger than 50 mm are free-living (Soemodihardjo 1974; Paul 1980a). Small queens secrete more byssus threads and re-attach much more rapidly than larger individuals. The rate of attachment is highest at 18°C and declines, and becomes more variable, at both higher and lower temperatures (Paul 1980a). Byssus production in *A. opercularis* is extremely sensitive to environmental conditions, such as the presence of pollutants in the water, so it makes a very sensitive bioassay for marine contaminants (Roberts 1973). Although the spat of *A. opercularis* retain the ability to byssally attach to a larger size than *P. maximus*, the detached spat are much more active and show a preference to climb up and attach to vertical surfaces. This behaviour provides the basis for a simple but effective method of separating spat of the two species taken from collectors (Paul 1985). Once they cease to form a byssus, adult *A. opercularis* remain much more active than *P. maximus*. They do not recess but rest on the seabed, with the more deeply cupped left shell uppermost, and are excellent swimmers throughout life (Ansell and Ackerly 1994), though swimming ability varies seasonally. In the warmer summer and autumn months, queens swim readily in response to approaching divers and fishing gear (Chapman et al. 1979), and to escape from predatory starfish (Stephens and Boyle 1978). Underwater observations have shown that queens swim when fishing gear is 1–1.5 m away, and are only caught in bottom trawls when they are off the seabed (Chapman et al. 1979; Chapman 1981). The importance of vision in stimulating swimming in *A. opercularis* is supported by the fact that daylight catches in trawl fisheries greatly exceed those taken at night. Although swimming can be an effective short distance escape response, queens are not capable of swimming large distances. In Loch Ewe, Scotland, queens could be stimulated to swim for up to 11 times in succession, during which they travelled a maximum distance of only 6.6 m before becoming exhausted (Chapman et al. 1979). In areas with strong water currents, repeated swimming may result in downstream dispersal, and this could account for some of the many fishermen's reports of queen scallops suddenly disappearing from a fishing ground.

A. opercularis has not been studied as extensively as *P. maximus*, probably because of its lower market value. However, some aspects of the physiology and genetics have

received considerable attention, and there have been several comparative studies of the two species. Feeding mechanisms of queens have been investigated, both in the field and in the laboratory (Vahl 1972; Mathers et al. 1979a; Lawrence 1993). While queens are unable to efficiently filter particles smaller than about 7 μm in diameter, they are able to pump large volumes of water at relatively low metabolic cost and show a flexible feeding response to changing dietary quantity and quality. The effects of temperature acclimation on the rates of oxygen consumption and filtration were studied by McLusky (1973), who suggested that 20°C was near the upper lethal temperature for this species. However, Paul (1980a) found the upper temperature tolerance ($LT_{50-48\text{h}}$) for large and intermediate sized queens was between 19–24°C, depending on the acclimation temperature, while for spat it was 24–25°C, and byssus production was at its maximum at 19°C. These experiments were all carried out on Scottish and Irish Sea populations so it would be interesting to investigate temperature tolerances in Mediterranean or Adriatic populations that are acclimated to higher temperatures. Reduced salinities ranging from 16–28‰ were lethal to *A. opercularis* after a 24 h exposure period, depending on the temperature and size of the animal (Paul 1980b). Mortality increased at extremes of temperature and spat had a slightly greater tolerance of low salinity than larger individuals.

Studies of the distribution and abundance of *A. opercularis* populations have been carried out in many areas throughout the geographical range (e.g., Brienne 1954; Ursin 1956; Pickett and Franklin 1975; Mason et al. 1979c; Franklin et al. 1980b; Piccinetti et al. 1986) but the Irish Sea stocks have been particularly well studied (Aravindakshan 1955; Watson 1971; Soemodihardjo 1974; Allison 1993; Veale et al. 2001). *A. opercularis* has a patchy, aggregated distribution, like *P. maximus*, but it occurs on a wider range of substrates and, when present, can occur at very much higher densities (Mason 1983). The life span of *A. opercularis* is shorter than that of *P. maximus*, with a maximum probably not exceeding 8–10 years and generally much less. In the Irish Sea queens reach a commercially acceptable size (50mm shell height) at an age of 14–18 months; beyond 4–5 years old the natural mortality rate is high and individuals more than 6 years old are rare on all fishing grounds (Brand and Prudden 1997). With so few year-classes present in the exploited populations, the success of the fishery in any year is highly dependent on the strength of recruitment. The spatial and temporal variability in year-class strength is considerably greater for *A. opercularis* populations than for *P. maximus* populations (Allison 1993). However, the main north Irish Sea queen fishing grounds have remained spatially persistent since the fishery began in 1969, although the areas of good recruitment within each ground vary from year to year.

Age and growth has been studied in many areas and the earlier data have been reviewed by Taylor and Venn (1978) and Mason (1983). Since then, Richardson et al. (1982) studied seasonal variations in growth of queens suspended at different depths, and Richardson et al. (1984) carried out an experimental study of the effects of iron ore suspensions and food on shell and tissue growth rates. More recently, Allison (1993) compared the growth rates of queens on different fishing grounds around the Isle of Man. He found them to be very variable, both spatially and temporally, and went on to develop a growth model that accounted for seasonal oscillations in the edible yield (Allison 1994). There have also been a number of studies of the growth of *A. opercularis* in suspended

culture in Galicia, NW Spain (Román and Acosta 1991; Lowe 1996; Román et al. 1999). The high growth rates achieved at high densities indicate that this species has good potential for aquaculture in the Galician rias.

Other aspects of the population dynamics of queen scallop stocks are generally poorly understood compared with the state of knowledge of *P. maximus*. Mortality rates have rarely been determined. Allison and Brand (1995) calculated instantaneous rates of total (Z), fishing (F) and natural (M) mortality from tagging for an Irish Sea queen population and found them to be 0.41, 0.21 and 0.20 per month, respectively. The calculated value of M is very high but includes incidental fishing mortality (F_i) resulting from gear damage. An estimate of M for an adjacent, largely un-fished area, based on age-frequency analysis, gave a value of only 0.036 per month (0.43 per year). If natural mortality on the fished ground was at a similar level, then F_i would account for most of the mortality calculated as M in the tagging study. Incidental mortality may therefore approach F in this fishery. Very high levels of F_i , often exceeding F and M, have been reported for some other scallop fisheries (e.g., Naidu 1988; McLoughlin et al. 1991) and highlighted the need to assess the full impact of gear damage on both target stocks and the environment. In recent years, this has been frequently investigated for various European scallop and queen scallop fisheries (Hall-Spencer et al. 1999; Bradshaw et al. 2000, 2001, 2002; Hall-Spencer and Moore 2000a, b; Veale et al. 2000b, 2001; Pranovi et al. 2001).

The main predators of *A. opercularis* are mostly the same species that prey on *P. maximus*, notably decapod crabs and starfish prey on adult queens, and a wider range of animals prey on the spat and juveniles. There is evidence from field and laboratory experiments that the two most important predators in the Irish Sea, *Cancer pagurus* and *Asterias rubens*, both feed preferentially on *A. opercularis*, rather than *P. maximus*, despite the better escape response of the queen scallop (Whittington 1993; Veale et al. 2000a). Pond (1992) has shown that the encrusting *Suberites* sponges that frequently colonise the shell of *A. opercularis* (Ward and Thorpe 1991) forms a protective-commensal relationship with the queen scallop, in which the sponge protects the scallop from predation by *Asterias rubens*, probably by reducing tube-foot adhesion. Diseases do not appear to be an important cause of mortality in *A. opercularis*. In a recent survey of healthy stocks, Lohrmann (2000) found few pathogens present in *A. opercularis* populations from five locations around the U.K., though there were more different parasites, and they generally occurred at high prevalences, than in *P. maximus* taken concurrently from some of the same sites. Rickettsiales-like micro-organisms were present in gill epithelial cells but the prevalence was much higher in queens from the English Channel (85%) than from those taken in the Irish Sea and the North Sea (<20%). Microsporidian spores were present in queens from all locations, but with a much higher prevalence (40%) at one Irish Sea site (Lohrmann et al. 2000). This is the first time a microsporidian infection has been reported in any scallop species. There have been some studies of heavy metal accumulation in *A. opercularis* (Bryan 1973; Topping 1973; Howard and Nickless 1978) and of the effects of iron ore suspensions on feeding and growth (Richardson et al. 1984) but there is no evidence of mortalities caused by environmental pollution.

Like *P. maximus*, *A. opercularis* is a simultaneous hermaphrodite with the prominent gonad containing a proximal creamy-coloured testis and a distal bright red ovary. The onset of sexual maturity occurs very early in this species, when they are about one year old (Soemodihardjo 1974). The annual reproductive cycle has been studied at various locations throughout the geographical range (Aravindakshan 1955; Ursin 1956; Soemodihardjo 1974; Broom and Mason 1978; Taylor and Venn 1979; Castagnolo 1991; Canales et al. 1995; Román et al. 1995; Peña et al. 1996). The general trend appears to be for a single annual spawning peak at the northern end of the latitudinal range and multiple peaks at the southern end, but local conditions can result in different spawning patterns in some closely located populations. For example, in the north Irish Sea, where the most detailed studies have been carried out, three more-or-less distinct peaks of spawning each year are characteristic of the inshore populations (Aravindakshan 1955; Duggan 1987; Wanninayake 1994); they generally occur in February–March, June–July and September–October, with the autumn spawning appearing to be the most important. However, for a deeper-water population farther offshore, Wanninayake (1994) found only two peaks, with no evidence of the autumn spawning. Instead, the spawning peaks were less well-defined and the redevelopment of the gonad through the autumn and winter proceeded some two months earlier than for the inshore population studied. In the smaller number of annual spawning peaks and the absence of an autumn spawning in the deeper water population, *A. opercularis* therefore resembles *P. maximus* populations studied concurrently on the same two fishing grounds. Despite the apparent importance of the autumn spawning on most north Irish Sea grounds, as indicated by studies of the reproductive cycle, most spat settlement on benthic epifauna and artificial spat collectors in this area over many years has come from spring or early summer spawnings (Brand et al. 1980; Paul 1981; Brand and Prudden 1997). Beaumont and Hall (1999), discussing the difficulty of artificially inducing *A. opercularis* to spawn in the hatchery, suggest that it may be a ‘dribble’ spawner, rather than a complete spawner, under natural conditions. This may well be the case with some populations where spawning and partially spawned gonads are present in most months of the year (Canales et al. 1995). Seasonal cycles of energy storage and utilisation have been described for queen populations from the west coast of Scotland (Taylor and Venn 1979) and the Irish Sea (Wanninayake 1994), and estimates of reproductive effort made for Bay of Brest populations (Lucas et al. 1978; Lucas 1982).

The population genetics of *A. opercularis* has received considerable attention. Unlike similar studies on *P. maximus*, allozyme electrophoresis has readily demonstrated genetic differentiation between queen populations on a relatively small geographical scale, and few studies have used DNA-based molecular techniques. After an early study by Mathers (1975) reported significantly different *Gpi* allele frequencies in queen populations from the west and east coasts of Ireland, Beaumont (1982b) carried out a more extensive study of queens from some 20 locations ranging from Norway to Brittany. Of the four loci investigated, one locus was monomorphic, and two showed little variation, but there were large differences in the frequencies of three alleles at a protein locus, *Pt-A*. From these data Beaumont proposed that there were at least four relatively genetically isolated populations of *A. opercularis* around the British Isles, namely (1) the north and west

Scottish coast, (2) the Irish Sea, (3) the west Brittany and west Irish coast, and (4) the English Channel. More recent workers have shown highly significant differences in allele frequencies between sites, both within and around the Irish Sea (Lewis 1992; Lewis and Thorpe 1994b). These, and several other studies, have also taken advantage of the fact that queens can be aged from shell rings to study the stability of gene frequencies between year-classes. The predominant situation appears to be one of consistency of allele frequencies within sites from one year to the next. This temporal genetic stability, coupled with highly significant geographical heterogeneity, suggests the possibility that populations could be predominantly self-recruiting (Lewis and Thorpe 1994a; Lewis and Thorpe 1994b), despite having a planktonic larval stage lasting several weeks. For many *A. opercularis* and *P. maximus* populations it seems likely that hydrographic mechanisms resulting in larval retention may restrict local genetic exchange (Heipel et al. 1998). Unusual hydrographic events may, however, bring an occasional influx of larvae from further afield, as occurred in the Irish Sea in 1979 when an uncommon allele appeared in only one year-class of queens (Macleod et al. 1985) following a short period of exceptional storm-force winds. Some other aspects of genetic variability have also been studied, notably variations in the level of heterozygosity. Beaumont (1982a) concluded that differences in heterozygote deficiency between year-classes of queens in a Scottish sea-loch were due mainly to selection acting at the larval and/or the juvenile stage. Beaumont and Beveridge (1984) and Beaumont and Zouros (1991) effectively rule out self-fertilisation as a major cause of heterozygote deficiency, while Lewis and Thorpe (1995) consider that allozyme heterozygosity may act as a buffer against developmental abnormality in queen scallop spat.

19.2.3 The Black or Variegated Scallop, *Mimachlamys varia* (L.)

Mimachlamys varia (L.) is a small scallop, rarely growing to a shell height exceeding 60 mm. The shell is inequivalve, with both valves convex. It has protruding ears, the anterior of which is much larger than the posterior, and there is a prominent byssal notch in the right anterior ear. The shell colour is very variable, ranging through off-white, yellow, orange, pink, red, brown, purple, dark green and grey to almost black, often with prominent irregular patterns in many colours. Both valves have 25–35 prominent radiating ribs, each bearing spatulate spines that are particularly well-developed near the strongly crenulated margin. There are also numerous concentric growth striae, with annual growth lines sometimes clear.

Mimachlamys varia usually lives attached by the byssus to shells, stones or boulders on coarse sand or gravel substrates, but it also attaches to rock faces (Rodhouse and Burnell 1979) and is frequently associated with dense banks of the horse mussel, *Modiolus modiolus* (Jones 1951; Roberts 1975) and the oyster, *Ostrea edulis* (Forester 1979; Burnell 1991). Unlike *Pecten maximus* and *Aequipecten opercularis*, adult *Mimachlamys varia* are usually byssally attached (Mahéo 1968; Soemodihardjo 1974), but they can detach the byssus and utilise similar escape responses to the other scallops, although they are not such powerful swimmers (Millward and Whyte 1992). The shells are often heavily colonised by epizoites, including algae, sponges and serpulids

(Rodhouse and Burnell 1979; Burnell 1983). Forester (1979) noted that dense growths of the sponge *Halichondria panicea* were common epizoites on *M. varia* on the Atlantic coast of Ireland. He showed that this partnership was a commensal-protective mutualism, the sponge benefiting from the scallop's feeding currents while protecting it from predatory starfish. Although *M. varia* can extend into deeper water (Tebble 1966), abundant populations appear to occur only within sheltered bays, in shallow water down to 10 m (Rodhouse and Burnell 1979). *M. varia* contributes little to European fisheries, except in some parts of France. Despite this, there has been much research on some aspects of its biology.

The most detailed series of studies have been carried out on a population of *M. varia* from Lanvéoc, Bay of Brest, France (Shafee 1979 1980a, b, 1981, 1982; Shafee and Lucas 1980, 1982), covering metabolism, growth and reproduction. Studies of growth are complicated by the presence of clear biannual recruitment, and the growth curves of spring and autumn spawned cohorts remain different throughout life (Conan and Shafee 1978). When various growth models were fitted to data for annual and seasonal growth, linear day degree models were found to be capable of predicting growth in shell height (Shafee 1980a). Empirical models using temperature, food availability and gonad index as independent variables showed that temperature and food together were decisive factors determining growth rates. There were also clear seasonal variations in the growth of body tissues, but this was not closely correlated with changes in shell height. Seasonal changes in gonad index and other quantitative aspects of the reproductive cycle were studied (Shafee and Lucas 1980), together with related studies on seasonal changes in biochemical composition and calorific content (Shafee 1981), and oxygen consumption (Shafee 1982). Data from these various studies were integrated to assess seasonal variation in the overall energy budget (Shafee and Lucas 1982), and to calculate reproductive effort (Shafee and Lucas 1980; Lucas 1982).

Growth and reproduction has also been studied for populations on the west coast of Ireland (Rodhouse and Burnell 1979; Burnell 1983; Burnell 1991; Burnell 1995). The life span of *M. varia* in this area is estimated to be 9–10 years. Growth characteristics, as shown by the parameters of the von Bertalanffy growth equation, were markedly different for *M. varia* in Lough Ine and Inner Roskeeda Bay. Seasonal growth at these sites was best described by a model incorporating temperature (as day degrees >9°C) and standing crop of phytoplankton (as chlorophyll-*a*). A population model was fitted and reproductive effort calculated for each age group in the population.

The reproductive biology of *M. varia* differs considerably from *P. maximus* and *A. opercularis* because *M. varia* is a successive protandric hermaphrodite (Lubet 1959; Reddiah 1962; Lucas 1965; Rodriguez et al. 1991). There is usually an imbalance in the sex ratio, with males predominating among small scallops and females among the larger animals. At any one time an individual may function as either a male or a female, but can change sex after spawning. For the Lanvéoc population, change of sex may occur within a single season or less commonly between successive seasons, and individuals may undergo several successive changes (Lucas 1965). In most areas where the reproductive cycle has been studied there appear to be two main periods of spawning each year, but the timing can differ between areas, and between years. For Bay of Brest and other French

populations there is a partial spawning in May-June and a complete spawning in September-October, but other intermittent spawnings can occur between May and September (Dalmon 1935; Lubet 1959; Buestel et al. 1979; Shafee and Lucas 1980; Dao et al. 1985c). In the northern Irish Sea, around the Isle of Man, the first spawning takes place about a month later than in French waters, while the second appears to be at about the same time or slightly later, extending into November (Reddiah 1962). On the west coast of Ireland the first peak of spawning activity occurs in late May or early June, at a similar time to the French populations, but the second is earlier, in early August, although an additional minor spawning occurs in September in some years (Burnell 1983, 1991). Burnell noted that the major spawnings coincide with peaks in chlorophyll *a* and appear to be triggered by temperature fluctuations of 1–2°C around 15°C that occur at spring tides.

The biannual pattern of spawning in *M. varia* is generally reflected in the pattern of spat settlement in collectors (Conan and Shafee 1978; Burnell 1991; Peña et al. 1996), although there was only one peak in settlement off the Isle of Man in 1993 and 1994 (Zhang 1996). However, good settlement in collectors has not been found to be a reliable predictor of good recruitment in the natural population (Buestel 1978). Furthermore, spat settlement does not appear to be closely correlated with the intensity of spawning as measured by the gonad index (Lucas 1965; Buestel et al. 1978), or with the population reproductive effort (Shafee and Lucas 1980). Larvae of *M. varia* have been reared under hatchery conditions (Le Pennec and Diss-Mengus 1985, 1987) and spat settlement occurs in about 25 days at 18°C (Burnell 1983). On the west coast of Ireland, where the second spawning usually results in the highest settlements, the higher mean temperatures in July and August appear to be more conducive to larval survival and settlement than the conditions in May and June (Burnell 1991). Burnell found that spat collectors need a period of 2–3 weeks immersion to develop a biofilm before they become attractive for larval settlement of *M. varia*, after which they continue to attract settlement for several weeks. He also noted that spat often settled on the calcareous tubes of *Sabella pavonina* that had settled on the collectors and suggested that this association may be important to *M. varia* spat.

There have been a few studies on aspects of the genetics of *M. varia* (Mathers 1975; Beaumont and Beveridge 1984), including a reciprocal transplant experiment (Gosling and Burnell 1988). In this latter work, there was genetic evidence of selective mortality when scallops from Loch Hyne on the south coast of Ireland were transplanted into Roskeeda Bay on the west coast. Baron et al. (1989) investigated the induction of triploidy in hatchery cultured *M. varia* with the aim of producing a strain that requires less energy and food for growth in areas of poor nutritional capacity. Although they obtained a high percentage of triploids (78.5%), their triploid larvae had a significantly higher mortality before metamorphosis than untreated diploid controls, and there was no difference in growth.

Other aspects of the biology of *M. varia* that have been investigated include studies of digestive cycles (Mathers et al. 1979b), feeding, and the structure and function of the labial palps (Beninger et al. 1990, 1991). The toxicity of silver and its bioaccumulation has also been investigated (Metayer et al. 1990; Berthet et al. 1992). Martoja et al. (1989) found that silver accumulated in the glandular cells of the primary byssus gland and

inhibited byssus secretion. *M. varia* was also one of several species of bivalve mollusc affected by organotin pollution in Mulroy Bay, Ireland (Minchin et al. 1987b).

Mimachlamys varia is a valuable commercial species in France and attempts have been made to manage natural stocks and replenish those depleted by overfishing (Letaconnoux and Audouin 1956; Dao et al. 1985c). Since very large numbers of *M. varia* spat often settle on artificial collectors, much effort has gone into cultivation from naturally collected spat (Buestel et al. 1978; Latrouite 1978; Latrouite et al. 1980; Dao et al. 1985c; Burnell 1991), but spat have also been reared in a commercial hatchery (Le Pennec and Diss-Mengus 1985, 1987). More recently, interest has been growing into the possibilities of cultivating this species in Spain (Cancelo et al. 1992; Peña et al. 1995; 1996; Cano et al. 1999).

19.3 FISHERIES

Scallops have been landed in Europe for more than 100 years but although directed fishing in most countries started in the 1930s, modern dredge fisheries only really started to develop in the 1950s and 1960s, based mainly on stocks of *Pecten maximus* and *Aequipecten opercularis* around the coasts of the British Isles and France (Mason 1983; Dupouy and Latrouite 1976; Dupouy 1978). Over the last 30 years the fisheries have expanded enormously, and other areas and other species have been exploited.

In recent years three species of scallop, *Pecten maximus*, *Aequipecten opercularis* and *Chlamys islandica*, have accounted for most of the catches in European waters. The fishery for *Mimachlamys varia* is small and concentrated in two areas in France, the eastern part of the Bay of Brest and the Perthus Charentes, near La Rochelle. Catches of the St. James' scallop, *Pecten jacobaeus*, make only a small contribution to European scallop landings, but this species is landed in many Mediterranean, Adriatic and Aegean ports and is undoubtedly under-reported or not identified to species in the official statistics. In some years more than 1,000 t has been landed in Chioggia market, Italy (Renzoni 1991), but the stocks declined in the 1990s due to over-fishing and the fishery was on the brink of commercial extinction (Mattei 1995; Mattei and Pellizzato 1996). In recent years landings of *P. jacobaeus* in Turkey have increased and 570 t was reported for 2000.

Total European landings of *Pecten maximus*, *Aequipecten opercularis* and *Chlamys islandica*, from 1985 to 2000 are shown in Fig. 19.1. This, and other figures in this chapter, is based on statistical data taken from the FAO Fishstat Plus database and from ICES Bulletin Statistique, supplemented with published and unpublished data from national sources. Where major discrepancies occur between the statistical sources, these have been resolved by discussions with colleagues involved in fisheries research. One problem in determining changes in the fisheries is the increasing proportion of scallops that are not attributed to species in the official statistics. This category, recorded in the statistics as 'scallop nei' (not elsewhere included), has increased steadily over the last 10 years and now accounts for nearly 20% of the total landings.

Catches of *Pecten maximus* declined slowly until 1990 but have since risen steadily and the 37,000 t catch for 2000 represents about 50% of total European scallop landings.

Figure 19.1. Total annual European landings (tonnes live weight) of *Pecten maximus*, *Aequipecten opercularis*, *Chlamys islandica* and other scallops (not identified to species in the statistics), 1984–2000. Based on data from FAO Fishstat Plus database, with additional data from Ø. Strand (personal communication).

Annual *Aequipecten opercularis* landings have fluctuated between 7–16,000 t, but after falling to a low level in 1995 and 1996, following poor recruitment in the Irish Sea, catches have increased again to some 15,000 in 1999 and 2000, representing 20% of European scallop landings. After the development of the large Norwegian fishery for *Chlamys islandica* around Jan Mayen, Bear Island and Spitzbergen in the mid-1980s, catches of this species peaked in 1987 but subsequently declined rapidly and now make up <15% of European scallop landings. Overall, total European scallop landings dropped sharply from 1987 to 1989, with the demise of the Norwegian *C. islandica* fishery, but since then there has been a fairly steady increase, due mainly to the increasing landings of *P. maximus*.

Catches of *Pecten maximus* from each of the main fishing areas between 1974 and 1998 are shown in Fig. 19.2. From 1974 to 1989 there was a marked decline in catches from both the east and west Channel grounds that was only partly offset by steadily increasing catches from the Irish Sea, Scottish west coast and northern North Sea grounds. Since 1990, catches have increased again on both the east and west Channel grounds, and with steady increases elsewhere, particularly on grounds to both the east and west of Scotland, the total *P. maximus* landings have increased greatly.

Figure 19.2. Annual landings of *Pecten maximus* (tonnes live weight) from European waters, 1974–1998, showing the landings taken from each major sea area fished. Roman numerals refer to ICES fishing areas.

Landings of *Aequipecten opercularis*, from the main fishing areas between 1974 and 1998 are shown in Fig. 19.3. The Irish Sea has always been the most important queen fishing area, contributing up to 80% of total annual landings. However, landings from the Faroes have increased steadily since 1975, with one massive fishery in 1990, and have contributed more than 30% to total queen landings in recent years. Elsewhere, queens are fished in many areas but these fisheries are generally sporadic. Although the main market for processed queen scallops is now in France, very few queens are caught in French waters. Overall, queen landings have been very variable from year to year, depending mainly on the success of recruitment. In the Irish Sea, poor recruitment, particularly of the 1992 year-class, resulted in a sharp drop in catches in the period 1994–1996, but the fishery has since recovered.

Gear, boats, fishing practices, areas fished and approaches to management differ in many respects from country to country. The development of the fisheries and their present status is described below for the main scallop and queen fishing countries. Although considered country by country, there is in fact considerable interaction between the fisheries due to the mobile nature of many modern scallop dredgers, and the traditional

Figure 19.3. Annual landings of *Aequipecten opercularis* (tonnes live weight) from European waters, 1974–1998, showing the landings taken from each major area fished. Roman numerals refer to ICES fishing areas.

lack of effort regulation in U.K. scallop fisheries. The Isle of Man fishery is considered first, and in the most detail. Though not the largest or most economically important fishery, there is a long, well-documented, history of both scallop and queen fishing in the waters round the Isle of Man, and many of the features described for the Manx fishery apply also to other fisheries.

19.3.1 Isle of Man

Fishing for *P. maximus* started close inshore off the west coast of the Isle of Man in 1937. After the war the fishery developed rapidly, particularly in the 1960s, as more and larger boats joined the fishery and gear developments enabled the boats to exploit rougher areas of seabed. The start of the *A. opercularis* fishery in 1969 was also a major influence on the exploitation of new scallop grounds. The distributions of the two species overlap in many areas, so scallops have subsequently been fished in many areas where they occur in densities that would not be viable, were it not for the additional queen by-catch. Since

the mid-1980s scallop fishing has taken place on a number of more-or-less discrete fishing grounds all around the Isle of Man, while the more restricted queen fishing grounds are mostly to the north, east and south of the Island (for maps see Brand et al. 1991a; Brand 2000).

In the early years, scallops were fished with relatively large (3 ft 6 ins–6 ft wide; 107–183 cm) dredges with a fixed tooth-bar, grouped together in ‘gangs’ on a heavy steel towing bar. However, ‘Newhaven’ spring-toothed dredges were introduced in 1972 and rapidly replaced fixed tooth-bar dredges as the normal gear. Then, in the early 1980s, individual dredge size was reduced to 2 ft 6 ins (76 cm), or sometimes 2 ft (61 cm), and these small spring-toothed dredges have subsequently become more-or-less universal throughout the British Isles, rigged to fish for either scallops or queens (Fig. 19.4a). Modern ‘Newhaven’ dredges fishing for scallops have 9 teeth on the standard 76 cm wide dredge, set 75 mm apart. Behind the tooth-bar the collecting bag is made up of a belly of steel rings (>75 mm internal diameter) and a netting back (100 mm stretched mesh) that extends forward ahead of the tooth-bar. As queen scallops do not recess into the seabed, and swim actively to avoid capture, they can be caught with a wider range of fishing gear (Mason 1983). In the early days of the Isle of Man queen fishery various types of dredge without teeth were tried but ‘Newhaven’ spring-toothed dredges rigged with shorter, more closely set teeth, and smaller ring diameter bellies were found to be efficient on the rough fishing grounds around the Isle of Man and were subsequently generally adopted. Newhaven spring-tooth dredges fishing for queens usually have 10 teeth on the standard 76 cm wide dredge, and belly rings of about 57 mm internal diameter (Fig. 19.4a). However, in the last few years a new type of toothless dredge, known as the ‘skid’ dredge, has been introduced and is gaining popularity. Skid dredges are a modification of toothed dredges, with each dredge frame mounted on ski-like runners and the tooth-bar replaced with a tickler chain (Fig. 19.4b). When fishing for scallops or queens, the number of dredges varies with the power of the boat, and while 4–8 per side is usual for the Manx fleet (Fig. 19.5), some very big vessels elsewhere pull much larger spreads of gear, up to 20 per side. Because of the large amount of bottom debris and invertebrate by-catch retained by the small-mesh bellies, boats dredging for queens use mechanical riddles on deck to sort the catch. On some fishing grounds bottom trawls are very efficient at catching queens in the summer months, when the queens swim actively to avoid capture, and some Manx boats trawl for queens for a few months each year. The trawls used are similar to groundfish nets but with heavier bobbin wheels or rock-hoppers on the groundline (Chapman et al. 1979; Brand et al. 1991a).

Management of fisheries in the north Irish Sea is complicated by the number of national jurisdictions involved. Management out to 12 miles around the Isle of Man is the responsibility of the Isle of Man Government, while the Republic of Ireland Government, and the U.K. Departments for England and Wales, Northern Ireland and Scotland all have jurisdiction in their respective areas. The Isle of Man Government has always taken a leading role in scallop fisheries management and maintained the strictest regime. Some of the measures introduced by the Manx Government in 1943, such as the closed season and minimum legal landing size (MLLS), were subsequently adopted by the U.K. Government and operate throughout the north Irish Sea (ICES area VIIa). The current closed season

Figure 19.4. Dredges used to catch queen scallops (*Aequipecten opercularis*) in the north Irish Sea. a). Newhaven spring tooth-bar dredge, 76 cm wide, with 10 teeth and 57 mm internal diameter belly rings. b). 'Skid' dredge with ski-like runners and tickler chains instead of a tooth-bar. Diagrams kindly supplied by Sea Fish Industry Authority.

Figure 19.5. A gang of four 'Newhaven', 76 cm wide, spring tooth-bar dredges attached to a towing bar with large rubber bobbins at each end. The dredges are rigged to fish for queen scallops with 10 teeth and 57 mm internal diameter belly rings.

runs from 1 June to 31 October inclusive (apart from Cardigan Bay off the coast of Wales where fishing is allowed to continue throughout June) and the MLLS is 110 mm shell length. Additional Manx legislation restricts fishing within the 3-mile limit to vessels under 50 ft (15.24 m) in length, and fishing for scallops is prohibited after 18.00 hours GMT or before 06.00 hours GMT on any day. The possession or landing of shucked scallop meat by any fishing boat is also prohibited and vessels dredging for species other than scallops are restricted to only a 1% by-catch of scallops. There are also a series of technical measures governing the gear. The aggregate width of dredges that a boat may use is limited to 25 ft (762 cm) in the 3-mile area and 40 ft (1,219 cm) in the 3–12 mile area. Within the 12-mile territorial sea it is prohibited to use scallop dredges that have more than 9 teeth, a tooth spacing between the internal edges of less than 75 mm, belly rings with a clear opening of less than 75 mm internal diameter, and a mesh size of less than 100 mm in the netting cover. French dredges with a diving plane are also banned. In view of the number of measures governing the scallop fishery it is perhaps surprising that there are no specific regulations restricting queen fishing, other than the overall gear size restrictions and the prohibition on boats >50 ft (15.24 m) within the 3-mile limit. However, processors do not usually accept catches that contain a high proportion of

queens less than about 55 mm shell height because it is not economic to process them. Since 1989, Isle of Man legislation has also prohibited dredging and trawling (but not static gear) within a small closed area of about 2 km² within the Bradda Inshore fishing ground off Port Erin. This area was closed to allow scientists from the Port Erin Marine Laboratory to assess scallop cultivation and stock enhancement, but has also proved an invaluable facility for studying the impact of dredging on benthic communities, and their subsequent recovery (Bradshaw et al. 2000, 2001).

The numbers of Isle of Man registered boats fishing for scallops and queens has fallen substantially from a maximum of about 70 in 1984 to about 30 in recent years. However, the average boat length has increased and more than 50% of active vessels are now >50 ft (15.24 m) which disqualifies them for fishing inside the 3-mile limit. Average engine power has increased more dramatically than length so the remaining vessels are able to tow more gear and exploit the offshore grounds more safely. However, this is not a modern, well-kept fleet, for many of the vessels are over 30 years old.

In addition to the Manx boats, there is a variable, but unknown, number of U.K. and Irish boats fishing scallops and queens in the north Irish Sea each year. The most important of these is a fleet of Scottish vessels operating from Kirkcubright; this includes several purpose-built dredgers with modern gear and catch-handling facilities that are probably the most efficient scallop and queen dredgers in the U.K. The Kirkcubright boats, and many other U.K. boats from other areas, are nomadic and fish wherever the best opportunities arise. The number of boats fishing in the north Irish Sea can therefore vary enormously, both within and between fishing seasons. No reliable data on fishing effort are available but there is no doubt that, overall, U.K. fishing effort on scallops has risen greatly in recent years as many more boats have turned to scalloping for at least part of the year when whitefish quotas are exhausted, or as a more economic alternative to *Nephrops* trawling in the winter months. Catches by the Manx fleet are landed daily, in the shell, processed on the Isle of Man and mostly exported fresh to continental Europe. Other boats operate from various ports in England, Wales, Scotland, Northern Ireland and the Republic of Ireland, landing daily or from 2–3 day trips, with the catches transported overland to shore-based processors.

The annual landings of scallops (*P. maximus*) from the north Irish Sea (Area VIIa), by country, over the period 1969–2001 are shown in Fig. 19.6. Overall, catches have been quite variable from year to year but rose to a high level of some 4000 t in 1980, fell to less than 2000 t by 1993, and rose again to nearly 4000 t in 2001. In the early part of this period, boats from the Isle of Man took the majority of the catch, but since 1980 boats from elsewhere, particularly Scotland and England and Wales, have taken an increasing proportion of the catch and the Manx share has declined to <30%.

Annual landings of queens (*A. opercularis*) by country, over the same period, are shown in Fig. 19.7. Overall, landings have been very variable from year to year with peaks in 1972, 1976, 1981, 1983, 1987, 1991, 1998 and 2001 and very poor fisheries in the period 1994–1996. These fluctuations in catch mainly reflect variable recruitment, but annual variations in fishing effort by the mobile U.K. fleet, and market demand, also have an effect. When the queen fishery first started in 1969 only Manx boats took part, but since the early 1970s increasing numbers of other vessels, particularly Scottish, have

Figure 19.6. Annual landings of scallops (*Pecten maximus*) (tonnes live weight) in the Irish Sea (ICES Area VIIa), by country, 1969–2001.

progressively taken the bulk of the catch and the Manx share has declined to less than 20%.

The proximity of these fisheries to the Port Erin Marine Laboratory has ensured that they are amongst the most thoroughly studied and best-documented scallop fisheries in the world (see, for example, Tang 1941; Mason 1957, 1958a; Gruffydd 1972, 1974a, 1974b; Murphy 1986; Brand et al. 1991a; Allison 1993, 1994; Brand and Allison 1994; Allison et al. 1994; Brand 2000; Beukers-Stewart et al. 2001a; Jenkins et al. 2001; Jenkins and Brand 2001). Biometric data is available, dating back to the start of the scallop fishery in 1937, and commercial catch and effort data from fishermen's logbooks, recorded on an unusually small spatial scale (5 x 5 nautical miles) has been collected for both scallops and queens since 1981. Two, large-scale, tagging experiments have been carried out on scallops (Brand and Murphy 1985, 1992; Allison 1993) and a smaller study on queens (Allison and Brand 1995), and these have provided estimates of spatial variation in exploitation and mortality rates. Stock assessments have been made using yield per

Figure 19.7. Annual landings of queen scallops (*Aequipecten opercularis*) (tonnes live weight) in the Irish Sea (ICES Area VIIa), by country, 1969–2001.

recruit models for a number of fishing grounds (Murphy 1986; Murphy and Brand 1987; Allison 1993) and annual reports on the fisheries and the state of the stocks are made to the Isle of Man Government (e.g., Brand and Beukers-Stewart 2002). In recent years there has been a large programme of research to investigate the environmental impact of scallop dredging (Brand et al. 1997; Brand 2000; Bradshaw et al. 2000, 2001, 2002; Veale et al. 2000a, b, 2001; Jenkins and Brand 2001; Jenkins et al. 2001).

19.3.2 Scotland

Commercial fishing for *Pecten maximus* in Scotland started in the Clyde sea area in the 1930s but it was not until the 1960s that it started to spread to other areas (Mason et al. 1991). As new grounds were discovered, more boats joined in and fishing spread first to the west of Kintyre in 1963, then to the north-west coast and Orkney and Shetland in 1967, followed by the Moray Firth in 1977. Since the early 1990s larger vessels have also

exploited extensive scallop grounds well offshore in the central North Sea, up to 200 km east of the Scottish coastline. Scallop dredging is therefore a significant fishery around almost the entire coast of Scotland, including the Western and Northern Isles. Total Scottish landings have averaged about 8,000 t in recent years, with a first sale value of some £13 million. Fishing for queens began in the Clyde in 1967, and in the Shetlands and the north Irish Sea in 1970, and these three areas, particularly the latter, continue to dominate queen landings in Scotland. The boats dredge for scallops using standard 2 ft 6 in (76 cm) 'Newhaven' spring-tooth dredges. Smaller vessels up to 16 m in length dominate the west coast fleet and generally tow 2–10 dredges per side. The Moray Firth and North Sea grounds are exploited mainly by larger vessels towing 10–14 dredges per side. In the early years the Scottish scallop fishery was dominated by dedicated scallop dredgers, but over the last decade increasing numbers of *Nephrops* trawlers have converted to scallop dredging in the winter months, particularly on the west coast grounds. Queens are also generally fished with spring-tooth dredges, with smaller belly rings, netting mesh and tooth spacing. Otter trawls have also been used in the Clyde and beam trawls have proved effective in Orkney and Shetland (Mason 1983). In some areas of Scotland, particularly the west coast, Orkney and Shetland, there are significant diver caught landings of scallops from shallow, inshore beds.

For management purposes Scottish fisheries have been divided into 8 management areas, namely the Irish Sea, Clyde, West Kintyre, North West, Orkney, Shetland, North East and East Coast. These areas differ considerably in size, exploitation history, stock structure and annual recruitment patterns. In recent years the North East management area has provided the largest landings, followed by the North West, East Coast, Irish Sea and West Kintyre. All Scottish waters are subject to the EU MLLS of 100 mm shell length and shucking at sea is banned. Since January 2000, EU rules have also required a minimum mesh size of >100 mm in the dredge netting back, and restricted the whitefish by-catch to 5% when dredging for scallops. In the Clyde area there is a statutory weekend ban on mobile gear, while a voluntary weekend ban operates to the west of Kintyre. A seasonal winter ban also operates from October to March in a number of west coast sea lochs and adjacent waters to protect nursery grounds for herring and plaice.

Since 1990, Scottish scallop fisheries have been increasingly affected by algal toxins that have resulted in area closures for food safety reasons, particularly in the most productive summer months. Paralytic shellfish poisoning (PSP) closures occurred in the 1980s but became more frequent in the 1990s on both the east and west coasts. Closures have generally been of 1–3 months and most commonly affected Orkney and the Foray Firth. However, in 1995, much of the eastern North Sea, including the Moray Firth was closed for over 2 months in mid-summer. Even more serious, however, was the accumulation of amnesic shellfish poisoning (ASP) toxins in 1999 that resulted in large-scale closures of Orkney, the Moray Firth and almost the entire west coast grounds (Campbell et al. 2001), including Northern Irish waters. Large areas of the west coast were closed in July 1999 and some remained closed to scallop and queen fishing for more than 9 months. As well as affecting the boats, the regularity and duration of these closures has become a serious problem to the Scottish processing industry, leading to the inability to service debt, the loss of skilled processing staff and disruption of established markets

(Denton 2000). Once lost, these markets may be difficult to recover in the face of cheap, but reliable, imports of farmed scallops into continental markets. It has been estimated that the direct cost to the industry of the ASP closure was about £10 million (Denton 2000). However, to date, no recorded case of any human illness in the U.K. has been attributed to ASP (Campbell et al. 2001).

The collection of statistical and biometric data for the Scottish fisheries is the responsibility of the Scottish Office Agriculture Fisheries and the Environment (SOAEFD), who hold long datasets for the main areas fished. These have been used periodically for stock assessments for the main fished areas (e.g., Mason et al. 1979b, c, 1980, 1981, 1991).

19.3.3 England and Wales

Scallops have been landed in England and Wales for over a century but it was not until the mid-1970s that a significant dredge fishery developed (Mason 1983), firstly in the western English Channel, then in the eastern Channel and later in the Irish Sea. The scallop fishery in the English Channel and western approaches remains the most important for England and Wales. This fishery has developed strongly since the late 1980s (Fig. 19.8), due mainly to increased exploitation of offshore grounds by large (28–35 m) ex-Dutch beam trawlers towing 14–20 standard 76 cm 'Newhaven' spring-toothed dredges per side. These vessels are owned by financial interests throughout the U.K. and form a mobile fleet, prepared to dredge for scallops and queens wherever the best opportunities arise. In response to this, local authority Sea Fisheries Committees, with the power to manage fisheries out to six miles, have introduced by-laws limiting the number and type of dredges that may be used in their districts. This has provided some protection to the inshore fishery, so vessels in the 8–15 m size range have continued to exploit the traditional inshore grounds successfully, while the numbers of 15–25 m vessels have fallen. Landings of scallops into England and Wales from the Irish Sea were high in the early 1980s, then declined, but have risen sharply since 1996, although a substantial proportion of these landings are from Scottish registered vessels. Queens are fished mostly in the Irish Sea, though there is a small fishery off the Yorkshire coast, landing mainly at Whitby.

The England and Wales scallop fisheries are subject to the EU MLLS of 100 mm shell length, apart from the Irish Sea and the eastern English Channel, where the MLLS is 110 mm shell length. From January 2000, the EU permitted fish by-catch when dredging for scallops was reduced from 10% to 5%. National legislation has also banned the use of French dredges with a diving plane, which were used extensively on certain grounds in the western Channel; these were banned because they retain high by-catches of protected fish species, particularly Dover sole. Proposed national legislation will also restrict the number and size of dredges to be used in the 6–12 mile zone. In response to growing concern about the displacement of effort from whitefish stocks into scallop fisheries, restrictive licensing for scallops was introduced throughout the U.K. in April 1999 for vessels over 10 metres. Under this scheme licenses were granted to any vessel that had caught more than 1 t of scallops in any year between 1 January 1994 and 31 May 1998.

Figure 19.8. Annual landings of *Pecten maximus* (tonnes liveweight) in England and Wales, 1974–2001, from each major fishing area. Roman numerals refer to ICES fishing areas. Data from DEFRA.

As a result of this low entry qualification, 454 U.K. vessels >10 m are currently entitled to fish for scallops. A process of consultation with the industry is now taking place to determine how restrictive licensing and further technical measures can be used to control the exploitation of scallops.

The Department for Environment, Food and Rural Affairs (DEFRA) is responsible for the collection of commercial catch statistics for the England and Wales fisheries. Scientists at the Centre for Environment, Fisheries and Aquaculture Science, an agency of DEFRA, are carrying out research aimed at assessing the state of scallop stocks in the English Channel (Dare and Deith 1991; Dare et al. 1993, 1994; Dare and Palmer 1994; Palmer 1995), but are hampered by the sparse nature of the biological data for this area.

19.3.4 Northern Ireland

Scallops have been landed in Northern Ireland since the 1920s but a commercial fishery was first established in 1933 and provided winter employment for up to 90 boats (Mason 1983). After the war the fishery remained at a low level until the 1980s but has since supported a small but locally important fishery with some 10–20 boats fishing mainly from Kilkeel, Portavogie, Donaghadee and Bangor. The grounds fished are mainly in the Irish Sea (ICES area VIIa), off the east coast of County Down between Ardglass and Larne (Briggs 1995), including Belfast Lough and parts of Strangford Lough. However, since the early 1990s there has also been a small summer fishery off the Londonderry and Antrim coasts, in ICES area VIa, which is not subject to a summer closed. For the Irish Sea grounds, the dates of the closed season (currently 1 June to 31 October) have generally followed those in operation elsewhere in area VIIa in order to prevent the diversion of effort onto Northern Ireland grounds. Similarly, the MLLS of 110 mm applies throughout Northern Irish waters. Since March 1997, the 'Conservation of Scallops Regulations (Northern Ireland) 1997' has also controlled the number, size, tooth number, tooth spacing, belly ring diameter and net mesh of dredges, banned French dredges, prohibited diving for scallops during the closed season and restricted the permitted by-catch of scallops to <1% when fishing for sea fish other than scallops. As Strangford Lough is an important marine conservation area, scallop dredging in the Lough is limited to the southern end, and only during the period 1 November–30 April.

Pecten maximus landings in Northern Ireland have generally been only a few hundred tonnes per year. However, they increased steadily in the late 1990s and in 2001 some 650 t were landed with a first sale value of £791,000 (Fig. 19.9). Most of this catch was taken from the Irish Sea (VIIa) grounds (shown in Fig. 19.6) but in recent years some 100 t per annum have been taken from the northern grounds in area VIa. In the first few years of the Irish Sea queen scallop fishery (1972–1976) some 500 t of *A. opercularis* per year were landed in Northern Ireland, but landings have since have been low, generally less than 100 t per year. Harmful algal blooms have also affected the Northern Ireland scallop fisheries in recent years, with short public health closures due to DSP and ASP toxins above the permitted levels.

The collection of data relevant to management of the Northern Ireland fisheries is the responsibility of the Department of Agriculture and Rural Development (DARD). Surveys of stock structure are carried out annually and scientific assessments of the fishery have been reported in a series of studies (Briggs 1980a, b, 1987, 1991, 1995).

19.3.5 Republic of Ireland

There is a very long history of scallop fishing in Ireland but the fisheries have been mostly on a very small scale, based mainly on small boats fishing numerous inshore beds in the bays around the south east, south and west coasts (Mason 1983). In recent years the main beds fished have been off Kilmore Quay, Dunmore East and the Saltee Islands on the south east coast, and in Roaringwater Bay, between Cape Clear and Sherkin Island,

Figure 19.9. Annual landings (tonnes liveweight) and first-sale value (£1000s) of *Pecten maximus* landed in Northern Ireland, 1989–2001 (from ICES areas VIa + VIIa). Data from DARD.

Dunmanus Bay, Bantry Bay, Berehaven Sound, Whiddy Island and Glengariff on the south west coast. Further up the west coast there are also large beds in Kilkieran Bay and Betraghboy Bay, near Galway. The fisheries can be fairly clearly divided into two distinct types: inshore and offshore (Fleury et al. 1997). The inshore grounds are exploited by boats of 7–10 m length and 40–120 hp, typically using two dredges 70–130 cm wide. The design of the dredges varies considerably and many are used without steel ring bellies, and are often towed by rope and hauled with pot haulers. These local fisheries are often exploited to the point of extinction, as the small multi-purpose boats will fish for very small daily returns during the winter months when no viable alternatives exist. The offshore fisheries off the south-east and east coasts are fished seasonally by part of the Irish beam-trawl fleet. These vessels are 18–25 m and 300–500 hp, and tow 10–16 standard 76 cm wide ‘Newhaven’ spring-toothed dredges. Many of the local fishermen exploiting the inshore grounds may not report their landings, so the official statistics are probably greatly underestimated. Reported annual landings of *P. maximus* in Ireland have rarely been more than a few hundred tonnes. Landings for the north Irish Sea (ICES area VIIa) by the offshore fishery are probably more reliable; since 1969 they have varied between 86–1611 t, with high landings in the period 1989–1992 (Fig. 19.6). A dense bed of queen scallops on the Kish Bank off the east coast produced a substantial fishery in 1970 (1,367 t) but was quickly fished out and queen landings since 1974 have been negligible (Fig. 19.7). Irish scallop fisheries are subject to the EU MLLS of 100 mm shell

length, and seasonal closures, a weekend ban on fishing and restricted daily fishing hours are also applied in some areas. Scallop dredging is also banned in parts of Mulroy Bay known as the North Water and Moross Channel in order to protect spawning stocks in this important spat collecting area.

19.3.6 France

With the main European market for scallops in France, fishing for scallops along the French coast has been an important economic activity for many years. In recent years some French 800 boats have fished seasonally for scallops (Dao et al. 1997). The French fishery for *Pecten maximus* can be divided into a number of different regions: the eastern Channel inshore grounds, particularly the Bay of Seine; the eastern Channel offshore grounds; the Bay of St. Brieuc and other western Channel grounds; and the Atlantic coast from the Bay of Brest to Pertuis Charentes. The fishery developed first on the Atlantic coast grounds in the 1950s but there was also fishing at this time along the Channel coast between Dieppe, Boulogne and the English inshore grounds (Ansell et al. 1991). Fishing then extended into the Bay of St. Brieuc in 1962 and the Bay of Seine a few years later. These two bays subsequently became the mainstay of the French scallop industry. In the Bay of St. Brieuc, catches increased steadily to 12,000 t in 1972 and there was a similar expansion in the Bay of Seine, while the traditional Atlantic fisheries declined to a very low level. In the Bay of Brest, for example, annual production dropped from 1,500–2,600 t in the 1950s to only 100–300 t after 1963. However, with strong landings in the western and eastern Channel, total landings of *P. maximus* in France rose to a peak of 25,300 t in 1973, but then declined steadily to a low of 5,077 t in 1990. Since then they have increased again, and for the period 1992–2000 have been fairly stable at 12–14,000 t. The detailed history of each fishery and the state of the stocks has varied from region to region, but all French fisheries now depend more-or-less exclusively on the exploitation of recruitment that occurs when the scallops are 2–3 years old (Dao et al. 1993).

In the Bay of St. Brieuc, the increase in scallop abundance that brought the start of the fishery in 1963 has been linked with the collapse of *Octopus* populations. *Octopus* were considered to be the main predators of scallops during the 1950s (Piboubés 1973), but they died off during the very cold winter of 1962/3 and never returned. Strong scallop recruitment between 1968 and 1973 resulted in a large increase in stock size, which led to the peak in productivity in the mid-1970s. Since then stock size and yield have varied with recruitment, though recent declines are considered to be due to over-fishing. Studies of water currents, and features of the reproductive cycle (Paulet et al. 1988), suggest that the scallop stock in the Bay of St. Brieuc is self-sustaining (Dao et al. 1993). Stocks in the eastern English Channel are spread over a large area but have followed broadly similar trends to the Bay of St. Brieuc. The only fishery in this area for which detailed knowledge is available is the Bay of Seine. Here the declines through the 1980s were followed by variable but increasing catches in the 1990s. Water current circulation modelling suggests that the Bay of Seine may be important in supplying larvae to the offshore grounds in the eastern Channel (Darby and Durance 1989; Dare et al. 1994). In the Bay of Brest, massive mortalities of scallops during the severe winter of 1962/3

(Boucher and Fifas 1997), followed by poor recruitment for nearly 30 years, resulted in low stocks until the 1990s, when a period of stronger recruitment, augmented by an extensive programme of cultivation (Dao et al. 1997; Fleury et al. 1997; Dao and Carval 1999), has brought about some increase in the stock. However, catches are still very low compared with historic levels. There have been very similar trends in the stocks on other French Atlantic scallops beds off Iroise, Ar Men, Concarneau, Quiberon and Belle Ile.

In the main fishing areas, annual stock assessments are made by IRFEMER to evaluate recruit and pre-recruit abundance, and spatial distribution. This is used as the basis for management strategies, which are decided between fishing representatives, administrators and scientists (Morin and Vigneau 1995). For the Bay of St. Brieuc, which has been most intensively studied, stock assessments are made in two ways (Dao et al. 1993): an annual evaluation of biomass in June using an experimental dredge with a diving plate and small rings in the belly (50 mm instead of the 85 mm used in the commercial fishery) and indirect methods including cohort analysis, catchability models (Fifas 1991), and equilibrium modelling of yield and fecundity per recruit. Since steady state models cannot take inter-annual recruitment variability into account, an empirical model of recruitment has been developed that includes the level of spawning stock biomass, the effects of fishing on the 0-age group, and the effects on recruitment of climatic conditions during the maturation and pre-spawning periods (Fifas et al. 1990).

French scallop fisheries are subject to EU and national regulations that restrict the MLLS to 100 mm, except for the eastern Channel where it is 110 mm, the maximum allowed fishing season to the period 1 October–15 May, and the minimum belly ring size to 72 mm. These regulations are strengthened by a complex series of local regulations that apply to so-called 'listed' beds. Fishing effort is controlled in various ways. Thus, the fishing season is shortened to run from November–April in the Bay of St. Brieuc and November–March in the Bay of Brest; the maximum permitted number of fishing days per week varies between two in the Bay of St. Brieuc and four in the Bay of Seine; and the number of fishing hours per day also varies from three-quarter to one hour in the Bay of St. Brieuc, two hours in the Bay of Brest and four to six hours on the inshore eastern Channel grounds. Total catch or individual daily quotas are also applied in some areas. Licences to fish are required on all grounds and the numbers of licences issued annually are restricted to 90 in the Bay of Brest, 259 in the Bay of St. Brieuc and 268 in the Bay of Seine. Boat size is also restricted to 12 m in the Bay of Brest, 13 m in Bay of St. Brieuc and 16 m in the Bay of Seine, and maximum engine power in these three fisheries is limited to 150 kW, 185 kW and 330 kW, respectively. Various types of dredge are used in the French fisheries including the typical 'French' dredge with a diving plane and fixed teeth, the 'heavy Breton dredge' and spring-toothed dredges. The permitted number, weight, width, tooth spacing and belly ring diameter of the dredges all vary between the different fishing grounds. Dredges with a diving plane are officially banned from all areas except the Bay of St. Brieuc, though they are apparently still used, while spring-toothed dredges are banned in the Sea of Iroise. The overall aim of these complex management regimes is to ensure regular landings from year to year, rather than to maximise yield per recruit.

Fisheries for *Aequipecten opercularis* and *Mimachlamys varia* are not so important or so well developed as those for *Pecten maximus*. The queen scallop fishery is sporadic and depends on good recruitment. Fishing is normally based on a single year-class and starts when a high-density aggregation is detected. The main grounds are in the western part of the Bay of Brest, the Bay of Camaret and the western Channel. The *Mimachlamys varia* fishery is more stable and the same boats fish for the two species, often at the same time. However, the main fishing areas for black scallops are in the eastern part of the Bay of Brest and in the Perthus Charentes. In the Bay of Brest the dredges are restricted to a maximum width of 1.8 m, a maximum weight of 120 kg and belly rings with an internal diameter of no less than 42 mm. Catches of *M. varia* in the Bay of Brest fluctuate between 200–400 t per year; in the Perthus Charentes they were historically some 800 t per year but the fishery collapsed between 1969 and 1991, though there has since been some recovery and annual catches were up to 200 t by 1997.

The management of the French fisheries has been supported in recent years by a substantial programme of research on recruitment determinism in scallops (e.g., Thouzeau and Lehay 1988; Thouzeau 1991a, b, c; Paulet et al. 1992). This includes work done within a broadly based series of studies in the Bay of Brest to explain inter-annual fluctuations of abundance of *Pecten maximus*, and with the ultimate aim of restoring water quality and marine resources in this heavily impacted ecosystem (Thouzeau and Chauvaud 1995; Paulet et al. 1997; Thouzeau et al. 2000; Chauvaud et al. 1996, 1997).

19.3.7 Spain

There has been a scallop fishery in the Galician Rias since at least 1870 but no landings data were available until 1962 (Román 1991). For *P. maximus*, annual catches of up to 300 t per year were recorded in the 1970s, but these declined to less than 100 t throughout the 1980s, before increasing again to a maximum of 675 t in 1996. In the 1960s there were also substantial catches of *Aequipecten opercularis* and some *Mimachlamys varia*, with combined totals of up to 700 t per year, but these subsequently dropped to such low levels that they are no longer recorded. There was also a short 'boom and bust' fishery for *P. maximus* in the Mediterranean, following the discovery of beds off Malaga in 1978 (Cano and Garcia 1985); catches in this fishery reached nearly 1,000 t in 1983, but by 1985 had declined to less than 100 tonnes. With such limited and unreliable supplies of pectinids from Spanish capture fisheries, and very strong market demand, the attention of scientists has increasingly turned to the possibilities of cultivation (Román and Acosta 1991; Román and Fernandez 1991; Román et al. 1996, 1999; Campos et al. 1999; Cano et al. 1999).

19.4 THE FUTURE

The history of scallop fisheries round the world indicates that natural scallop fisheries are very difficult to manage successfully. The reasons for this are numerous, but relate to three features of scallop fisheries: the biological characteristics of scallops themselves, the lack of appropriate management models and the common property nature of wild scallop

resources (Perrin and Hay 1987). Scallops have distinct habitat preferences, live in aggregated distributions and are relatively immobile. This means that they are predictably located by fishermen and easily caught. In addition, their method of reproduction, long planktonic larval life and environmental sensitivity results in large annual and spatial variations in spat settlement and survival to recruitment. In consequence, large fluctuations in stock abundance are characteristic of scallops and this is compounded in some species by the short natural life-span. These features of scallop populations make traditional fishery assessment methods that were mainly developed for finfish difficult to apply or inappropriate (Caddy 1989b; Orensanz et al. 1991). The common property nature of wild scallop stocks applies to most marine fish stocks but is of particular relevance to immobile shellfish species. Unless there is the political will to enforce strict limited entry restrictions, scallop stocks in the open sea are common property resources and, as stocks decline, it is in the rational self-interest of individual fishermen to increase, rather than decrease, their fishing effort, since the consequences of over-fishing are shared by all participants (Berkes 1985). This conflict between personal and communal benefit has been termed 'the tragedy of the commons' (Hardin 1968) and is an important factor leading to over-capitalisation and over-fishing in scallop fisheries (Perrin and Hay 1987).

At present, natural fisheries for *Pecten maximus* in Europe are nearly all fully exploited or over-exploited. With increasing exploitation, the older year-classes have progressively disappeared and all fisheries in France, and most in the U.K. and Ireland, are now dependent on fishing the recruiting year-classes. With the natural variability in recruitment, this has led to 'boom and bust' fisheries and instability of supplies for fishermen and processors. Scallop densities have also fallen markedly so that, in the north Irish Sea for example, the density of scallops on most grounds is now less than 3 per 100m² at the start of the fishing season and less than half that at the end of the fishing season (Wilson and Brand 1995). As stocks declined, fishermen have purchased larger, more powerful, boats capable of operating farther offshore and pulling larger gangs of dredges in order to maximise catches. In consequence, European fishermen now use large quantities of diesel fuel, pulling large spreads of gear over enormous areas of seabed, in order to gather up the very sparsely-distributed stocks of scallops. The high prices paid for scallops have made it possible to continue fishing on low densities but, in doing so, the toothed dredges used throughout Europe kill and damage many other animals on the seabed, change the physical nature of the sediments and modify benthic habitats and communities (Bradshaw et al. 2000; Brand 2000; Hall-Spencer and Moore 2000b; Veale et al. 2000b).

In order to preserve scallop stocks in the face of increasing exploitation, fishery management bodies throughout Europe have introduced progressively more strict regulatory regimes. European capture fisheries are also facing increasing competition from cultivated scallops. To date, the generally low-value species of cultivated scallop that have been imported, frozen, into European markets from countries such as China and Chile have competed directly with queen scallops (*Aequipecten opercularis*), but have not made a great impact on the market for fresh, high-value 'coquille St. Jacques' (*Pecten* spp.). The main supplies of *P. maximus* continue to come from capture fisheries, but this situation is likely to change in the next few years. Despite early demonstrations of the

feasibility of collecting the spat and culturing scallops and queens in France, Ireland, Scotland and the Isle of Man (e.g., Minchin 1976; Ventilla 1977a; Ventilla 1977b; Buestel et al. 1979; Buestel and Dao 1979; Brand et al. 1980; Paul et al. 1981; Wieland and Paul 1983; Norman and Ludgate 1995), commercial cultivation has been slow to develop and total European production of farmed pectinids is still under 500 t per year. Production is steadily increasing but large-scale production has been inhibited mainly by the shortage of spat. However, this is likely to change in the next few years for there are now several well-funded projects to develop hatchery culture of *P. maximus* in France, the U.K., Ireland and Norway. In addition, a brood stock of *P. maximus* has been imported into Chile (Illanes et al. 1999) with the aim of eventually supplying high value 'coquille St. Jacques' to the French market.

With the problems of managing natural stocks in the face of increasing exploitation, together with increasing competition from cultivation, European capture fisheries face an uncertain future. In all fisheries, the boats now fish under strict management controls that greatly restrict their fishing effort and prevent them operating with high economic efficiency. As cultivated scallops become available in quantity it will become increasingly difficult for traditional capture fisheries to compete economically. In order to promote more productive, economically efficient fisheries – and to prevent the widespread ecological impact of scallop dredging on seabed communities – there is growing evidence to suggest that the future of scallop fisheries may lie with closed area management (Horwood 2000). Seasonal closure of scallop fishing grounds have been applied for many years in Europe, and elsewhere, but the conservation value of seasonal closures for scallops and benthic communities is limited unless they are combined with strict control of fishing effort. Rotational closures, however, with a cycle of several years, can be used to prevent both growth and recruitment over-fishing (Myers et al. 2000, National Research Council 2001), and appear to be particularly suitable for scallop fisheries management, with or without stock enhancement. The Japanese have long used rotational fishing of small closed areas, in combination with predator clearance and stock enhancement, as part of their seabed cultivation technique (Ventilla 1982). These techniques have subsequently been used elsewhere, most notably with Japanese assistance in Tasmania (e.g., Thompson 1994; Thompson et al. 1995) and New Zealand, where short rotations (<4 years) have been successfully employed, together with re-seeding, to increase yield per recruit, maintain a stable fishery and sustain full-time fishermen (Arbuckle and Metzger 2000). Developments have been slower in Europe, but a collaborative scheme between government and fishermen's organisations in France, involving stock enhancement and rotational fishing, is now contributing to the recovery of scallop production in the Bay of Brest (Dao and Carval 1999). If this proves to be economically viable, similar ventures are likely to follow elsewhere, particularly on grounds close inshore.

Of more interest to capture fisheries, however, are the possibilities of using large-scale closed areas as a fishery-management tool, without stock enhancement. This was recently given a major boost by the report of a 14-fold increase in scallop (*Placopecten magellanicus*) biomass on Georges Bank that followed a 4-year closure to any gears capable of retaining groundfish (Murawski et al. 2000). This increase in scallop biomass was, in fact, a fortuitous outcome of large-scale area closures designed to protect depleted

groundfish stocks, but it was remarkable because it took place during a period of only moderate to below-average scallop recruitment. Even greater increases in *Pecten maximus* biomass have been recorded in the small Isle of Man closed area, compared with the fished area outside, albeit after a substantially longer period of closure (Brand and Beukers-Stewart 2002). In addition to increases in scallop density and biomass, rotational closures for <5 years can increase habitat complexity, and the production and diversity of benthic communities (Collie et al. 2000; Bradshaw et al. 2001), though the communities are likely to be dominated by mobile, robust, fecund and fast-growing opportunists. Longer rotational closures (5–10 years) would be needed to allow slower growing, less fecund species to proliferate (Collie et al. 1997; Bradshaw et al. 2002). However, to protect the most vulnerable and long-lived species, and the complex communities that develop on biogenic reefs and beds of horse mussels (*Modiolus modiolus*), serpulid worms (*Serpula vermicularis*) and maerl (e.g., *Lithothamnion corallioides* and *Phymatolithon calcareum*), permanent closures are generally necessary (Magorrian 1995; Moore et al. 1998; Collie et al. 2000; Hall-Spencer and Moore 2000a, b). Although permanently closed areas deprive fishermen of grounds, there can be some benefits to adjacent fishing grounds through the export of pelagic larvae and the ‘spill-over’ of juveniles and adults dispersing around the edges (Horwood et al. 1998; Hall-Spencer et al. 1999; National Research Council 2001). It therefore seems likely that the future management of near-shore waters will involve series or networks of closed areas of different sizes, closed for different periods and with differing objectives concerned with the conservation of fishery resources and marine communities.

Although there has been a substantial amount of research on short and long-term ecological impacts of scallop dredging (for example, European studies include Eleftheriou and Robertson 1992; Hall-Spencer et al. 1999; Brand 2000; Hall-Spencer and Moore 2000a; Bradshaw et al. 2000, 2002; Veale et al. 2000b, 2001), comparatively little information is available on the recovery of benthic organisms or habitats after closure to fishing (Collie et al. 2000; Bradshaw et al. 2001). As closed areas are introduced, supporting research will be required in many topics. For example, properly replicated large scale experiments will be required to evaluate the effectiveness of closed areas and determine the time scale of recovery for important species and habitats (Jennings 2000; National Research Council 2001). Studies will also be needed to evaluate factors such as the size, shape, connectivity and overlap of closed areas (Jennings 2000; Roberts and Hawkins 2000). Diversion of fishing effort could have major effects on scallop stocks and the benthos outside closed areas (Bradshaw et al. 2001), and this will also need to be evaluated in order to prepare schemes to minimise harmful impacts. To inform decisions on the siting of closed areas, a better understanding of scallop recruitment mechanisms is essential so that sources of scallop recruitment, rather than sinks, are conserved. Research is also needed to devise methods for assessing the extent to which closed areas export larvae, juveniles and adults to surrounding beds. Finally, it will be important to seek ways of limiting fishing effort and of modifying gear to reduce the damage it causes when closed areas are re-opened.

ACKNOWLEDGMENTS

I am very grateful to many European colleagues who have provided data and permission to quote from unpublished reports, particularly Richard Briggs, Dave Palmer and Guillermo Roman, together with Bill Lart, Partick Berthou, Ross Campbell, Julie Maquire and other members of the ECODREDGE research project. My thanks are due to Christine Drewery of the Sea Fish Industry Authority for her superb drawings of the dredges in Fig. 19.4. It is a pleasure to acknowledge also the continued financial support of the Isle of Man Department of Agriculture, Fisheries and Forestry for much of my research on scallops.

Chapter 20

European Aquaculture

Mark Norman, Guillermo Román and Øivind Strand

20.1 INTRODUCTION

The success of scallop aquaculture development in Japan created interest in scallop culture in Europe in the 1970–80s (Buestel 1981; Dao et al. 1999). The main species of interest were *Pecten maximus* and *Aequipecten (Chlamys) opercularis*, while *Chlamys varia*, *Chlamys islandica* and *Flexopecten flexuosus* have later also been considered for farming. These species are distributed along most Atlantic, Mediterranean and North sea coastlines (Figure 20.1). Today scallop culture is on an industry developmental level in Britain, France, Norway, Ireland, Italy and Spain. The commercial production of cultured scallops is still low, less than 500 tonnes a year. The culture of *P. maximus* in Norway and *C. islandica* in Iceland and Norway are covered in the Chapter 20 (Scandinavia).

Most of the work on scallop culture reviewed in the early 1980's focused on natural spat collection and farming by suspended culture operations (Berry and Burnell 1981; Paul et al. 1981; Wieland and Paul 1983). With the Japanese scallop aquaculture model and technology as a basis, several adaptations and experimental developments were undertaken with the aim of reducing the high cost of production associated with a long grow out, European labour costs and the high cost of materials.

Most of the experimental and development work was centred on areas where wild spat could be collected. In Scotland this was in the Rassay Sound off the Isle of Skye, while in Ireland it was in Mulroy Bay, County Donegal where significant catches of *P. maximus* were reported in the late 1970's (Minchin 1981, 1983). Other focus areas for aquaculture development were those areas with declining traditional fisheries such as the Rade de Brest, France and Connemara, Ireland.

In Spain, research is in progress to determine the feasibility of cultivating scallops found in two regions, the galician Rías Baixas and the coast of Malaga. From an historic point of view, the most important areas for mollusc production are the Rías Baixas in Galicia, NW of Spain. The Rías Baixas are wind protected, deep and narrow bays, where high primary productivity ($250\text{--}537\text{ g C m}^{-2}\text{ y}^{-1}$) (Bode and Varela 1998) and mild temperatures ($12\text{--}20^{\circ}\text{C}$) are recorded. A small-scale culture in this area supplies the market with about 10–20 tonnes of *P. maximus* annually. Experiments are being performed with *C. varia* and *A. opercularis*.

The highest *P. maximus* landings in Spain are recorded in Malaga. The region has an open shore with frequent easterly and westerly winds, which hinder the use of rafts. Recently, mooring of long-lines for mussel culture allowed the start of experiments for hanging culture of *P. maximus* and *C. varia*. Other species, such as *A. opercularis* and

Figure 20.1 Map showing main scallop aquaculture locations in Europe.

Flexopecten flexuosus are present in the Malaga area, but presently are not considered as research targets for commercial culture.

20.2 PECTEN MAXIMUS

The first aquaculture operations in Europe in the 1970's started with attempts to collect natural spat, following the Japanese model (Ventilla 1982). In Ireland and Britain, locations with a regular spat-fall were identified (Brand et al. 1980; Minchin 1981; Paul et al. 1981; Fraser 1983) and commercial collection programmes established. These methods are currently used to supply culture operations. Based on an extended study of settlement patterns of the great scallop, *P. maximus*, and other benthic species in relation to spatio-temporal variability of environmental factors in the Bay of Brest, Chauvaud et al. (1996) recommended improvements on the efficiency of spat collectors (physical and structural criteria), to collector placement, and on the intensity of biotic interactions at the postlarval stage.

Induction of synchronised spawning by rising broodstock held in suspended nets to shallower depths of warmer water was proposed by Minchin (1993) in order to improve

conditions for collection of scallop spat within sea-loughs. However, this is not a technique currently used by industry.

The amount of spat from natural collection programmes in Scotland and Ireland has varied each year for the past twenty years, from several thousand to several million (Scottish Executive 2001; J. Slater, pers. comm.). This irregular supply of spat has been caused by a range of factors including; organo-tin pollution; insufficient brood stock; lack of commercial markets for spat (Minchin et al. 1987).

In France, the failure of natural spat collection forced the restocking programme (Buestel et al. 1979) to develop hatcheries, nurseries and intermediate culture. The development of commercial scaled spat production in hatchery started in 1983, resulted in a production of annual production between 1988 and 1995 of 10 million spat, and has increased in more recent years to 25 million spat (Dao et al. 1999). Production of larvae and spat were previously done in laboratory scale (Comely 1972; Beaumont et al. 1982), but the French experience has been a reference for most other hatcheries in Europe (Fleury et al. 1997; Dao et al. 1999; Strand and Parsons, Chapter 21). The genetic aspects of hatchery rearing of the scallop *P. maximus* were reviewed by Beaumont (1986).

Devauchelle and Mingant (1993) reviewed information of reproductive biology of the scallop, *P. maximus*, and summarised the experience during ten years of an intensive aquaculture program in France for the development of spat production in hatchery. They presented data on how environmental factors sustain gametogenic activity at different times of the year, biochemical changes associated with gametogenesis, the consistency of egg quality and development of a simple test to predict egg quality.

After the production of postlarvae (2 mm) in hatchery-nursery, intermediate culture of spat in cages in the sea (2–30 mm) and seabed culture at densities of 10 m² until dredging 30–36 months later when they reach the marketable size of 100 mm shell length. Production cost calculations of the French production model showed that a survival rate of 30% after sowing was required to gain economic feasibility (Paquette and Fleury 1994).

Studies on culture of juvenile great scallops held in suspended nets in Bertraboy Bay, Ireland (Wilson 1987) and of spat (5–14 mm shell height) held indoor and fed cultured algae (Laing 2000) suggest that growth in culture conditions is mainly regulated by water temperature, rather than the amount of food available. Laing (2000) showed that as temperature increased, the scallops consumed a bigger ration, and the highest ration that they consumed efficiently determined their maximum growth rate. This is supported by Chauvaud et al. (1998) studying effects of environmental factors on the daily shell growth of juvenile *P. maximus* from the Bay of Brest. Growth was mainly regulated by bottom-water temperature, salinity and, to a lesser extent, river flows, rather than food. However, scallop food intake and growth were high when the algal concentration did not exceed a critical threshold, dependent on the dominant species and sedimentation rate of diatoms (Chauvaud et al. 2001). They observed events of slow growth during and after diatom blooms (*Rhizosolenia delicatula* and *Chaetoceros sociale*) and dinoflagellate (*Gymnodinium* cf. *nagasakiense*) blooms.

Intermediate culture is a necessary stage in *P. maximus* culture, which is usually performed in suspension. However, suspension cage culture of the pectinoid form of pectinids (Waller 1992) shows delayed growth after some time or when reaching a certain

size (Paul et al. 1981; Slater 1995). This is perhaps due to changes in the natural habitat, lack of sediment for recessing, or to the negative wave effect as Lodeiros et al. (1999) observed in *Euvola ziczac*. This is one reason why the trend is towards bottom culture of the pectinoid form of pectinids. However in some regions the environmental conditions or techniques allow suspension culture to commercial size in suspended cages as described in Malaga (Cano et al. 2000) or by ear-hanging (Paul 1988; Román and Fernández 1991; Gallagher 1999). In Ireland, stocking density and type of nets was shown to have a clear effect on growth and carbohydrate content in scallops (50 mm shell height) grown in suspended culture (Maguire and Burnell 2001).

Generally, scallops are not ear-hung until they have reached a shell height of 55 mm or more (Ventilla 1982; Dadswell and Parsons 1991; O'Connor et al. 1999). According to Gallagher (1999), the minimum size should be higher than 50 mm, excessive fouling should be avoided and culture duration should not be more than two years. Several studies have reported heavy fouling on the scallops in ear hanging (Minchin 1975; Cano et al. 2000) and particularly the settlement of *Balanus* sp. have caused high mortality.

In Galicia, Román et al. (2001) ear-hung juveniles of 66.6 mm mean shell height in September. The scallops were detached from collectors as 26.6 mm spat by the middle of November the previous year. In spite of the fact that no cleaning operations were performed at all during the growth period, the scallops grew well. By the end of May the next year, they were 81.2 ± 9.3 mm in shell height (14.5% commercial size), and by mid October they had reached 91.0 ± 9.7 mm height and the meat content (muscle plus gonad) was 24.4 ± 9.1 g. Roughly two years after detachment from collectors, 60.9% of the scallops had reached commercial size. Survival was 75.8% by May and 50.5% by October.

Stocking density and type of nets was shown to have a clear effect on growth and carbohydrate content in scallops (50 mm shell height) grown in suspended culture (Maguire and Burnell 2001).

The great scallop, *Pecten maximus*, is considered to be one of the most precious members of the scallops, and there is a large European market for live large size animals. Given the problems related to mortality, shell deformation and low growth, and high costs of farming this scallop in suspended culture, seabed culture has been regarded as the most feasible culture method in central and northern Europe (Paul et al. 1981; Lake et al. 1987; Minchin 1991; Dao et al. 1999). Cano et al. (2000) considered Fuengirola, Malaga, in southern Spain as the only place in Europe where suspended great scallop culture would be profitable by producing commercial scallop of 10 cm in shell length in approximately 18 months.

20.3 *AEQUIPECTEN OPERCULARIS*

In Galicia the most abundant scallop species obtained on collectors is *Aequipecten opercularis* at a rate of 25–200 per bag (Ramonell and Malvar 1993; Acosta et al. 1999; Román et al., unpublished data). In Malaga collection has been unsuccessful.

Spat collection in Scotland typically yields a mixture of *A. opercularis* and *P. maximus* spat (Paul et al. 1980). *A. opercularis* on-growing trials using standard

Japanese equipment and various adaptations demonstrated the suitability of these species for suspended culture. Farming this species in Scotland has been technically successful but production costs at times exceed the market price of wild caught scallops. There have been several marketing innovations including the marketing of "Princess scallops", partially grown (15–18 months from settlement), that are sold whole to be prepared in a similar manner to mussels. There are currently a number of farms using hanging culture techniques to produce *A. opercularis* in the sea lochs of western Scotland (Scottish Executive 2001).

20.4 *CHLAMYS VARIA*

In Spain, small numbers of *C. varia* has been reported to settle on collectors in Galicia (Román et al. 1987; Ramonell et al. 1990; Ramonell and Malvar 1993; Román et al. 1996).

In the Rade de Brest, Brittany there is a traditional dredge fishery for *C. varia*. Stock enhancement (bottom culture) using hatchery-produced seed (Louro et al. 2003) has been attempted. Small seed were released but with very poor survival. However, subsequent trials using similar size seed that had attached to substrate (broken roof tiles) in tanks prior to seeding significantly improved survival (J-C. Dao, pers. comm.).

20.5 SUMMARY

All aspects of scallop culture have been the subject of a considerable amount of research effort in several European countries. This research and development effort has been in a range of economic and industry climate; from Norway with little or no traditional or modern shellfish farming to France and Spain with large, well established industries for other species of bivalves.

Despite many technological advances, a large-scale scallop culture industry has not been successfully developed in Europe.

A number of factors have been identified as constraints to the emergence of such an industry. These include; the relatively long grow out period for king scallops; the high production cost of hatchery seed; an inconsistent supply of wild seed; low market prices for queen scallops (*Aequipecten* spp.); and high labour costs associated with hanging culture.

These constraints are the subject of research and development programmes in Norway, Ireland, France, Spain and the U.K.

Chapter 21

Scandinavia

Øivind Strand and G. Jay Parsons

21.1 INTRODUCTION

The commercial exploitation of scallops in Scandinavia, which includes Norway, Denmark, Sweden, Faroes, Iceland, and Greenland (Fig. 21.1) is moderately recent. Commercial fishing activity began in Iceland in 1969, the Faroes in 1971, and in the mid 1980's it began in Greenland and Norway (Table 21.1). In Denmark, only by-catches of scallops have been reported. From a modest start of 402 metric tonnes (t) in 1969 (Table 21.1), representing 0.3% of the global scallop landings (FAO 2000), the fishery for this region increased to 60,580 t, which corresponded to 8.1% of the world's total scallop harvest in 1987. This position was rather short-lived and in 1996, the catch of 20,596 t corresponded to 1.2% of the global scallop landings.

Three species of commercial interest *Chlamys islandica* (Muller), *Aequipecten opercularis* (L.) and *Pecten maximus* (L.) occur in the waters of northern Europe. The Iceland scallop (*C. islandica*) has a northern boreal distribution. The other two species have a boreal-temperate distribution. The queen scallop (*A. opercularis*) is fished in the Faroes and a fishery for the great scallop (*P. maximus*) exists in Norway. *C. islandica* is found in concentrations great enough to be exploited on a large scale in Iceland, Greenland and Norway. All three species have a commercial potential for aquaculture in Scandinavian waters, and considerable effort is being conducted on aquaculture development of *P. maximus* in Norway. *C. islandica* and *P. maximus* will be the main species dealt with in this chapter.

21.2 CHLAMYS ISLANDICA

21.2.1 Biology

Chlamys islandica is the northernmost species of the family Pectinidae and is distributed in the northern boreal or subarctic transition zone (Ekman 1953). It has been described as circumpolar in its distribution and its occurrence in the north Pacific from Alaska to Puget Sound, Washington (Wiborg 1963; Abbott 1974; Bernard 1983) has been questioned by Waller (1991). In the western Atlantic, it is distributed from the Arctic seas to southern Massachusetts (Abbott 1974; Serchuk and Wigley 1984). In the eastern Atlantic it is found from Spitsbergen south to Lofoten Islands, Norway (Wiborg 1973; Wiborg et al. 1974) and from Greenland, Iceland and Jan Mayen (Ockelmann 1958; Wiborg 1963; Kjolholt and Hansen 1986) east to the Barents and White seas (Fig. 21.1)

Figure 21.1. Scandinavia and Greenland waters.

(Wiborg 1963; Zenkevitch 1963). In Norway relict populations are found in fjords along the coast south from Lofoten Islands to the southern part of the west coast (Greve and Samuelsen 1970).

The Iceland scallop is found off the western coast of Greenland (Pedersen 1988a), ranging from Qaanaaq (Thule) (76°N) in the north (Lubinsky 1980; Pedersen 1988b) to Nanortalik on the southernmost coast (Fig. 21.1) (Pedersen 1988b). Its distribution off eastern Greenland is restricted to the southeastern coast and a relict population in the Franz Josephs Fjord (Ockelmann 1958). *C. islandica* is distributed all around Iceland except the south coast (Eiríksson 1997). However, the main distribution is rather discontinuous and almost entirely limited to fjord areas. The major Norwegian distribution is located north of the Lofoten Islands where it occurs in coastal and fjord areas, in the deeper waters of Bear Island, Spitsbergen and Jan Mayen (Wiborg 1963; Wiborg 1973; Wiborg et al. 1974; Rubach and Sundet 1988; Strand and Vølstad 1997).

Near the coast it is found on the inner sides of fjords with one or two shallow sills and low bottom temperatures of about -1.5°C to 9°C (Wiborg 1962; Wiborg 1963; Wiborg and Bøhle 1974; Eiríksson 1997). It is found in depths of 10–250 m; however, the largest concentrations occur in waters <100 m (Wiborg 1963; Venvik and Vahl 1985; Eiríksson

1997). *C. islandica* occurs on hard coarse sediments, consisting of sand, gravel, shells, and occasionally clay and fine sand (Wiborg 1962; Wiborg 1963; Vahl and Clausen 1980; Eiríksson 1997). These areas are often associated with strong currents and the scallops are invariably attached to stones or shells (Wiborg 1963; Vahl and Clausen 1980).

The Iceland scallop is a dioecious species (Wiborg 1963). Ripe female gonads are a pinkish hue and the male gonads are white. Male gonads are heavier than females, yet this has not been shown to occur throughout the year (Wiborg et al. 1974; Thorarinsdóttir 1993). Scallops are sexually mature at two and a half to six years of age (Sundet and Vahl 1981; Vahl 1981a; Vahl 1982; Thorarinsdóttir 1993), faster growing individuals reaching maturity first (Vahl 1981b). Wiborg (1963) and Pedersen (1988a) found the sex ratio to be 1:10 for Iceland scallops from Norway and Greenland, respectively. Scallops from Jan Mayen had a ratio of males to females of 0.8:1 (Rubach and Sundet 1988). The onset of spawning in northern Norway and in Breiðafjörður in Iceland varies annually from the end of June to the beginning of July (Skreslet and Brun 1969; Skreslet 1973; Gruffydd 1976a; Sundet and Vahl 1981; Sundet and Lee 1984; Thorarinsdóttir 1993). Furthermore, spawning occurs over a very short duration (about two weeks) (Skreslet 1973; Gruffydd 1976a; Sundet and Lee 1984; Thorarinsdóttir 1993). Gruffydd (1976a) observed shallow water scallops to spawn first, quickly followed by animals in deeper regions. Skreslet and Brun (1969) reported no difference with depth yet suggest that larger scallops may spawn earlier than smaller animals. Spawning appears to be triggered by short-term variations in temperature brought about by vernal meltwater discharge (Skreslet 1973).

Gonads start to recover immediately after spawning. In northern Norway spermatogenesis occurs only from March to October and oogenesis occurs throughout the winter months as well (Sundet and Lee 1984). The gonad weight of both sexes increases most rapidly in the spring from March to May (Skreslet and Brun 1969; Sundet and Vahl 1981; Sundet and Lee 1984). Thorarinsdóttir (1993) found that spermatogenesis in scallops from Breiðafjörður occurs during two periods of the year, from July to October and from February to June. However, in contrast to the Iceland scallops from northern Norway oogenesis did not continue throughout the winter.

This species is highly fecund and eggs are externally fertilised. The planktotrophic larvae spend up to 10 weeks, from late June to the end August, in the plankton before settling out (Gruffydd 1976a; Wallace 1982). Scallop larvae can detect salinity gradients and avoid lower salinity waters (Gruffydd 1976a). They can tolerate levels <80% ambient seawater. Settlement, onto artificial spat collectors, commences in September in both Norway (Wallace 1982) and Iceland (Thorarinsdóttir 1991). The metamorphosed larvae, which are about 305 µm, are capable of byssal attachment (Gruffydd 1976a).

Growth rates in *C. islandica* vary seasonally. The highest annual growth rate and net growth efficiency occurs in the spring (Sundet and Vahl 1981; Vahl 1981b) when the scallop utilises a large portion of the annual spring phytoplankton bloom (Vahl 1980a; Vahl 1980b; Thorarinsdóttir 1994). This is the period when Iceland scallops are also metabolically most active (Vahl 1978). Seasonal growth rates can be explained by variations in the proportion of particulate organic matter (POM) to particulate inorganic matter (PIM) (Vahl 1980a). Iceland scallops can effectively retain particles as small as 7 µm (Vahl 1973) but they can not preferentially select POM over PIM. As the ratio of

PIM increases, the scallops are not able to obtain sufficient food to sustain high growth rates. *C. islandica* has its greatest growth efficiency during the first six years of life (Vahl 1981b) and age-specific growth rates were highest for three and four year olds (10–11 mm yr⁻¹ in scallops from Balsfjord, Norway) (Brun 1971).

Growth rates are available for several populations of scallops off northern Norway, Bear Island banks (Bjørnøya), Spitsbergen, Iceland and Greenland. Icelandic populations of *C. islandica* have the fastest growing scallops. A five-year-old scallop from northwestern Iceland was 50 mm in shell height and a ten-year-old 84-mm (Eiríksson 1988). The fastest growth reported in Norway occurred off Andamsfjord, northern Norway, where a five-year-old was 39-mm shell height and a ten-year-old 82-mm (Wiborg 1962; Wiborg 1963). Bear Island banks, Balsfjord and Korsfjord (northern Norway) have approximately the same growth rates, a five year old being 35–40 mm and a ten year old 70 mm (Wiborg 1963; Wiborg 1973; Vahl 1981b). Growth around Bear Island is quite variable, the northern beds having greater growth than the southern or eastern areas, respectively (Wiborg 1973). Growth in scallops from northern Spitsbergen was 30 mm and 60–65 mm for five and ten year old scallops, respectively (Wiborg et al. 1974). The growth rates of *C. islandica* on the Mitra bank (northwest Spitsbergen) are the lowest, 25 mm for a five year old and 50 mm for a ten year old (Wiborg et al. 1974). Growth of scallops from western Greenland was slower than Iceland, yet comparable to Spitsbergen (Pedersen 1988a).

The adductor muscle (meat) weight for a given size scallop is larger in areas with faster growth rates (Wiborg 1963; Wiborg et al. 1974). Growth rates are influenced by depth; Wiborg (1973) showed that scallops found at 75–105 m grew better than at depths >105 m. The Iceland scallop is capable of limited swimming. Wiborg (1963) and Gruffydd (1976b) found that medium sized scallops (30–40 mm) tend to swim most often, but Vahl and Clausen (1980) report that all sizes (20–80 mm) move equally often in the field. Swimming speed is proportional to size and all sizes swam more often at higher current velocities (Gruffydd 1976b). Scallops moved an average of once every thirty-one days (Vahl and Clausen 1980) and are invariably attached by their byssal threads (Wiborg 1963; Gruffydd 1978). Although swimming is infrequent, there is some evidence that this species migrates (Wiborg 1963; Vahl 1982) especially into inner fjords (Gruffydd 1976b). A survey along a transect of Ulfsfjord showed an increase in the size of scallops from the outer to the inner fjord (Wiborg 1963).

The natural predators of *Chlamys islandica* include starfish, *Asterias rubens* (Brun 1968), cod (Wiborg 1973) and eider ducks, *Somateria* spp. (Brun 1971).

In the early 1960's, Wiborg (1962) and Wiborg (1963) were the first to survey scallop beds to determine their population structure. Several northern Norwegian fjords from Balsfjord to Neidenfjord were surveyed using a six foot Baird scallop dredge and a four foot Baird mussel dredge. A wide size range of scallops (10–100 mm) were present; however the majority of animals were greater than 60 mm. While there probably was some gear selectivity against the smaller scallops, the population was still dominated by larger individuals. Wiborg and Bøhle (1974) reported that several other populations of Iceland scallops in the northern Norway region were also composed of larger scallops, e.g., at Kvænangen, 80% were between 55–75 mm. At Kvænangen and Kraksund, they

found that the size distribution of scallops remained unchanged when surveyed in 1963 and in 1967. The distribution of Iceland scallops off Bear Island in 1968 and 1969 were also mainly composed of larger scallops, 91% and 85%, respectively, in the 55–85 mm range (Wiborg 1973). The average size distribution of scallops decreased with depth on beds in this area. Wiborg et al. (1974) re-surveyed this area again in 1973 using a larger commercial scallop dredge and found that all the scallops were greater than 60 mm. The size frequencies of *C. islandica* off Spitsbergen were predominately composed of scallops in the 60–80 mm range (Wiborg et al. 1974). The size range was smaller for scallops from Mitra bank (40–70 mm). This reflects the slow growth for this area as mentioned above. In Jan Mayen, 64% of the scallops caught were >65 mm (Rubach and Sundet 1988). The size distribution of scallops from eight locations in Breiðafjörður, western Iceland and five different depths at Sletta, northwestern Iceland all had a similar pattern with respect to location and depth (Eiríksson 1988). The majority of scallops were >65 mm. In Greenland the size distribution of scallops was strongly skewed to the larger scallops in the range of 60–110 mm with the majority being from 80–100 mm (Pedersen 1988b).

Wiborg (1963) determined the age of *C. islandica* by counting the alternating light and dark bands on the shell surface. However, Johannessen (1973) found that the lines produced on the ligament (resilium) were a more reliable and accurate method of ageing. Maximum longevity in the Iceland scallop is reported to be over twenty years (Vahl 1981a; Vahl 1981b; Vahl 1982).

The age composition of *C. islandica* populations generally corresponds to their size distribution (Wiborg 1973). Iceland scallops from northern Norway ranged from two to twelve years, with the majority being eight or older (Wiborg 1963). At Bear Island banks and off Spitsbergen, the majority of *C. islandica* were between the ages of ten and sixteen (Wiborg et al. 1974). In western Greenland, 40% of the scallops are over 21 years, which led Pedersen (1988a) to conclude that it is an accumulated virgin population.

Few data are available concerning Iceland scallop population densities. Wiborg (1973) estimated densities, from scallop dredge tows, to be as high as 80 m⁻² for Bear Island, with an average of about 10 m⁻². Some areas around Spitsbergen, which can be as high as Bear Island, also average 10 scallops m⁻² (Wiborg et al. 1974). Densities in inner Porsangerfjord and outer Balsford can reach as high as 60 m⁻² and 50 m⁻², respectively (Wiborg and Bøhle 1974). Densities at Balsford decline towards the inner fjord (Wiborg 1963). A detailed study of scallop density in Balsford using SCUBA and randomly placed quadrats by Vahl (1981c) demonstrated that the spatial distribution is highly contagious and fits the negative binomial distribution. Estimates of density of scallops from all age classes ranged from 56 m⁻² to 70 m⁻². In a later study, Venvik and Vahl (1985) found a mean density of 75 m⁻². Earlier studies on the distribution of Iceland scallops around Bear Island and Spitsbergen noted a low and irregular recruitment (Wiborg 1973; Wiborg et al. 1974). They based their observations on the low abundance of small scallops. Vahl (1981c) reports that *C. islandica* are not fully recruited in to the adult population until four years of age. Furthermore, recruitment can be highly variable, success being dependent on the density of the adult population already established (Vahl 1982). For existing beds, this suggests that recruitment will be low. However, if a

favourable habitat is made available, e.g., by an attack of predators (Brun 1968), then a massive colonisation of juvenile scallops could take place (Vahl 1982; Vahl 1985). Pedersen (1988a) has estimated a recruitment of 3–4% for scallops from western Greenland.

The patterns of variation that have been found at selected allozyme loci support the suggestion that populations of *C. islandica* in the Northeast Atlantic are genetically structured (Fevolden 1989; Fevolden 1992; Galand and Fevolden 2000). These studies include scallops from Jan Mayen, northern Norway, Spitsbergen, Bear Island (Fevolden 1989; Fevolden 1992), Kap Kanin (Russia), Breiðafjörður (Iceland) and Fauskangerpollen (southwestern Norway) (Fig. 21.1) (Galand and Fevolden 2000). The relict population from Fauskangerpollen was genetically most distinct from any of the other populations. In contrast with findings for several other bivalves, but in accordance with observations for other pectinids, Fevolden (1992) were not able to show any increase in heterozygosity with age, nor were positive growth-heterozygosity correlations demonstrated.

Little information is available on the mortality rates of Iceland scallops. Vahl (1981c) estimated the natural instantaneous mortality rate (M) of fully recruited scallops from Norway to be 0.17 yr^{-1} . This was calculated from the slope of the regression of the natural logarithm of mean density of year classes over time. From an estimate of egg production (no. m^{-2}) and back calculating the density of age-group four to density at settlement, Vahl (1982) obtained an estimate of larval survival to be 0.00005%. This assumes the same mortality rate in all age classes and an instantaneous population growth rate of zero.

21.2.2 Fishery

The commercial exploitation of *Chlamys islandica* in Iceland, started in 1969 and quickly reached a peak total catch of 7,400 t in 1972 (Table 21.1). The harvest in subsequent years declined to between 2,784 t and 4,427 t due to a decline in the price of scallops in the U. S. market. In 1978 after the introduction of mechanical shuckers, the catch rebounded and increased to the historical maximum of 17,068 t in 1985 (Table 21.1), of which 12,128 t were caught in Breiðafjörður (Fig. 21.1) (Eiríksson 1997). After 1985–1986 the annual landings decreased to a stable level of 8,000–12,000 t. Fishing effort in the 1980s and early 1990s was high, resulting in a 30–40% decline in stock abundance indices, and a 25% decrease in CPUE in Breiðafjörður between 1983–1993 (Eiríksson 1997; Anonymous 2000). Since 1993, the older component of the Breiðafjörður stock has seemingly remained stable, accompanied by an increase in CPUE due to improved fishing gear.

Scallops are caught, for the most part, inshore in fjords and bays. When the fishery commenced it was centred off the northwest coast but quickly shifted to the western coast after rich new beds were discovered. The main fishing grounds are concentrated on scallop beds in Breiðafjörður at depths of 18 to 46 m (Eiríksson 1997). Catches from this area now account for 85–90% of the total landings. The other main fishing areas include Arnafjörður, Ísafjörður and Húnaflói in northwestern Iceland (Eiríksson 1997; Anonymous 2000).

The vessels formerly used in the Iceland fishery are traditional boats (10–20 m), which were converted over from shrimp trawlers and gill-netters (Venvik and Vahl 1985; Eiríksson 1997). The Breiðafjörður fleet is composed of multipurpose trawlers or gill-netters with a crew of 4–7 and one 1.5–2.7 m dredge, depending of size of boat (Eiríksson 1997). Most dredges are British types introduced during the 1970's and modified, especially in connection with the rapid expansion of the Breiðafjörður fishery (Eiríksson 1997). The dredges are similar in size as the original British prototypes, but it is up to three times heavier.

The Icelandic dredge was developed in the 1980's, primarily for use in the Ísafjörður and Húnaflói area (Eiríksson 1997). It is equipped to fish on both sides, and with rolling bars this dredge slides more easily over rough bottom, large stones and boulders.

Tows are made from the stern at a speed of about 2 knots and are maintained for a five to ten minute duration in the Breiðafjörður area where catch rates have generally been high. Tows of up to 30 minutes are quite regular, especially in the smaller fjord fisheries (Eiríksson 1997). The dredge is hauled in on the side. They use a warp ratio of 5–10:1 in order to increase the stability of the tow (Eiríksson 1988). The catch is machine washed and sorted before it is landed in 300–500 kg lots in aluminium tanks or bags for machine shucking and processing the next day. The scallop processing plants are located at the ports of landing.

In the plant, mechanical shuckers de-meat the shells and then clean the rim and gonad from the adductor muscle. Most scallops were destined for the United States market until 1988, after which they were increasingly exported to France, including the roe-on French market (Eiríksson 1997). The meats are size and quality graded prior to packing. The most common method of preservation of scallops to be stored is by quick-freezing. Processing for the roe-on market involves increased manual handling following mechanical shucking, though this production increases the yield from 10–12% up to 15–18%.

The scallop fishery is strictly managed by both seasonal and area quotas, and a series of resource and exploratory surveys (see Eiríksson 1997). These measures have prevented the stock from being over-exploited and resulted in a well-managed and stabilised scallop fishery.

A fishery for the Iceland scallop commenced in western Greenland in the autumn of 1983 (Pedersen 1988a; Pedersen 1988c; Pedersen 1988d). The fishery increased from 410 t in 1984 to 1,693 t in 1985, and until 1992 the annual catch was lower than 1,086 t (Table 21.1). After the implementation of quota regulation for the main fishing areas, the catches have been from 1,176 t to 2,342 t. There are seven main fishing areas in western Greenland, including: Nuuk, Sisimiut, Attu/Tugtulik, Diskofjord, Mellemfjord, Mudderbugten and Sønder Upernavik. Based on exploratory surveys, the fishery is managed by quotas in Nuuk, Attu/Tugtulik and Mudderbugten. The scallop fishery is regulated by licensing, minimum shell size and a yearly quota (Pedersen 1988a). Resource (stock assessment) surveys are carried out in order to assess the stock biomass and to make recommendations on catch levels (Pedersen, pers. comm.). In 1995 stock assessment in the Nuuk area (Figure 21.1) estimated the biomass to be 4,400 t, a reduction from an estimated 8,500 t in 1988.

Scallops are mainly harvested for the roe-on market (Pedersen 1988c). The smaller boats land the scallops whole and deliver the scallops to fish plants in Nuuk and Paamiut where they were manually shelled. This represented 45% and 6% of the catch in 1985 and 1986, respectively. The rest of the landings were caught by larger vessels where the scallops were shucked onboard (Pedersen, pers. comm.). In western Greenland scallops are harvested throughout the year but most of the fishery takes place during the months of November to May (Pedersen 1988c).

Iceland scallops were found in substantial quantities in some fjords in northern Norway already about a century ago (in Strand and Vølstad 1997). The scallop was used as bait for local fisheries (Wiborg 1963; Wiborg and Bøhle 1974), but no data are available on the size of this fishery. A small fishery for human consumption existed near Kvænangen in the early 1960's and Richardsen (in Venvik and Vahl 1985) estimated the total catch to be approximately 500 t. The fishery did not persist due to a poor market and underdeveloped fishing and processing technologies, but the scallop beds at depths of 15 to 60 m in Balsfjord, Kvænangen and Porsanger were considered to have fishing grounds of commercial potential. Wiborg (1973) and Wiborg et al. (1974) found that even larger beds occurred in the Bear Island, Spitsbergen and Jan Mayen areas in depths of 40 to 100 m. However, cost-efficient gear for harvesting scallops in offshore areas did not exist at the time.

In 1985, the large scale commercial harvest of scallops began with 1,192 t being harvested that year (Table 21.1), and it increased rapidly as ocean-going ships discovered large quantities of scallops at Jan Mayen (Strand and Vølstad 1997). The gear and techniques were borrowed from Canada, the United States, Iceland, and the Faeroes. Fishing effort was subsequently switched to scallop grounds off Bear Island and Spitsbergen. However, scallop shells from this area are encrusted with barnacles, which caused problems in the mechanised processing of the scallops. During the first year only 3–4 vessels participated in the fishery, but effort quickly expanded, peaking at 27 vessels during 1986 and 1987. Subsequent participation dropped to 13 vessels in 1988, 3–4 in 1989–1990, 2 vessels in 1991 and 1 vessel in 1996. Since 1997, Iceland scallops have not been landed in Norway. The numbers of fishermen varied from about 10–12 on the smaller vessels to 36 on the larger ones. The daily catch often exceeded 600 t for the most efficient vessels.

A total of 11 vessels, 10–14 m in length, were licensed for fishing in the coastal areas of northern Norway, while 34 vessels participated in the offshore fishery between 1985 and 1992. Ocean-going vessels, ranging in length from 29 to 69 m, were mostly modified factory trawlers, fresh fish and shrimp trawlers, purse seiners, longline vessels and supply ships from the oil industry. The larger of the specially designed ships typically operated three dredges simultaneously, and sophisticated instrumentation to optimise fishing effort (see Strand and Vølstad 1997). The boats had up to three mechanised production lines for onboard processing and freezing of scallops. Crews onboard these boats could fish for 24 hours a day.

When the fishery began, the boats used a single-side action dredge (2.5 m wide) from Iceland, that was towed at 2 knots. Afterward, catch efficiency was increased through use of a double-action dredge and higher towing speed. The dredge was a modification of US

and Canadian dredge types and was towed at 4–5 knots with equal efficiency on both sides (Strand and Vølstad 1997).

During the fishery for Iceland scallops few regulations existed to protect the stock from over-exploitation. Inside the straight protection line along the coast of northern Norway, the fishing for Iceland scallops was restricted to 1 August–1 March. For 1985–1994, the total catch quota was 500–700 t round weight. Since 1995 the catch quota has been 250 t round weight, but the catch has been minimal (Table 21.1). In 1986, bounded catch reporting by logbooks was implemented. In 1987, the first coastal scallop bed, south of Tromsø, was closed. Fishing was prohibited inside a protection zone extending 4 nmi from the coastline of Spitsbergen. Outside this zone, no regulations were in effect for registered vessels participating in the Barents Sea scallop fishery in 1985. In 1986 restrictions preventing new boats from entering the fishery were implemented. In 1987 a lower size limit of 65 mm was introduced for all areas, and, because stocks were depleted, scallop beds were closed at Jan Mayen. In 1989, a limited area of these beds was reopened for fishing, while the scallop beds at Bear Island and Møffen (Spitsbergen) were closed. Subsequent catches have been from reopened areas regulated by a limited fishing period and a total catch quota. In 1993 exploratory fishing conducted at Kanin Bank (Russia) (Fig. 21.1) in collaboration with the Polar Research Institute of Marine and Oceanography in Murmansk, revealed scallop beds of commercial interest. Of the catch landed in Norway in 1996, 5,500-t whole weight were taken on the Kanin Bank.

Fevolden (1989) cautioned that a conservative approach to management of the Iceland scallop should be taken by considering each of the main areas (Jan Mayen, Spitsbergen, Bear Island and northern Norway) as if they were separate genetic units.

Norway exported most of their scallops, as a frozen product, to French and U.S. markets, but since 1987–1988 exports to France dominated.

21.2.3 Aquaculture

The cultivation of *Chlamys islandica* has been considered in Iceland, Greenland and Norway as a possible method of increasing the production of scallops in the area. Techniques for collecting Iceland scallop spat using artificial techniques have been tested successfully in Balsfjord, northern Norway (Wallace 1982) and in Breiðafjörður, Iceland (Thorarinsdóttir 1991). Using bags filled with nylon monofilament line, Wallace (1982) collected moderate numbers of *C. islandica* spat (average about 500 spat/net) in Balsfjord, Norway. Improved collection of spat occurred by placing the bags within 10 m of the bottom. Thorarinsdóttir (1991) collected 100–150 spat/net at a depth of 10 m off the bottom in Breiðafjörður, and observed heavier settlements on 0.2-mm than on 0.4-mm monofilament. Settlement, onto artificial spat collectors, commences in September in both Norway (Wallace 1982) and Iceland (Thorarinsdóttir 1991). After the first year, spat grew to an average size of 7 mm and 9 mm in Norway and Iceland, respectively, with the greatest rate of growth occurring from May to September. Larvae of *C. islandica* have been raised under laboratory conditions (Gruffydd 1976a) using the standard methods of Gruffydd and Beaumont (1972). However, spawning of adults has been difficult until the period in which natural spawning occurs. In 1986–1988 the University of Tromsø

conducted research on artificial spat production of Iceland scallops in a laboratory-scale hatchery, but it was not successful.

Subsequent to spat collection is the culturing of this species by either suspension or bottom culture. Growth of *C. islandica* in "Netlon" mesh bags held in suspension in northern Norwegian waters has been shown to be depth dependant (Reinsnes 1984; Wallace and Reinsnes 1984); growth being fastest at about mid-depth. Wallace and Reinsnes (1985) attributed these depth differences to variations in seston content. The greater amount of food in the upper water column leads to a higher growth rate for scallops held in suspension compared to bottom populations (Wallace and Reinsnes 1984; Thorarinsdóttir 1994). The market size of 60–70 mm was reached in 3–4 years in northern Norway (Wallace and Reinsnes 1985) and estimated to require 4 years in Breiðafjörður (Thorarinsdóttir 1994), compared with 6–8 years for scallops growing in the wild. Thorarinsdóttir (1994) considered the 4 years required to reach market size to be too long to warrant the additional costs associated with the suspended culture. There are currently no efforts to cultivate *C. islandica* in Iceland.

The first commercial-size farm culturing scallops was established in northern Norway in 1985 (Strand and Vølstad 1997). In 1987–1989 a total of 14,000 spat collectors were set out by this farm, and as many as 20,000 spat/collector bag were obtained. This farm was intended as a model for the development of an industry based on cultivating Iceland scallops in northern Norway. Farms conducting growth trials were subsequently established along the coast. Afterward, spat production declined as methods of handling the collectors were insufficient, but some higher productivity was obtained by removing spat from the collectors after 2 years instead of 1 year. In early 1990's the model farm was shut down due to low productivity, and farming activities along the coast declined. Spurred by the recent effort to develop shellfish farming in Norway, Iceland scallops are again being considered for cultivation.

Bottom culture is not considered to be a practical option due to the low natural growth rates, taking at least six years to reach commercial size (60 mm) (Wallace and Reinsnes 1985). Furthermore, while *C. islandica* is not a highly mobile species (Gruffydd 1976b; Gruffydd 1978), natural predators (Brun 1968; Brun 1971) also present an added problem to a concentrated bottom grow-out program. In Greenland, experimental transfers of *C. islandica* from slow growth areas to fast growth areas were performed to evaluate the feasibility to regenerate overfished scallop grounds (Engelstoft 2000). It was concluded that the possible benefit of transferring scallops did not warrant the cost associated with the operation.

21.3 PECTEN MAXIMUS

21.3.1 Biology

In Scandinavian waters *Pecten maximus* is found from Lofoten Islands in northern Norway (69°N) down to Kattegat (58°N) (Fig. 21.1) (Jagerskiöld 1971; Wiborg and Bøhle 1974; Høysæter 1986). It also occurs around the Faroes (Nicolajsen 1997). On the west coast of Norway, *P. maximus* is mainly found between depths of 5 to more than 30 m.

Along the southern coast the scallops are more scattered and appears to have a deeper distribution. In the Skagerak-Kattegat area it is mainly found between depths of 25–50 m, and is not considered to be a common species (Christensen 1979). The distribution in Skagerak and Kattegat is believed to be limited by hydrographical conditions, particularly large variations in temperature and salinity resulting from an influx of cold brackish water from the Baltic sea during late winter and early spring. They are more common along the western coast of Norway, northwards to about 67°N. The largest concentrations are found at 15–30 m. In Froan (64°N) maximum densities of 5–6 scallops m⁻² have been observed.

The reproductive cycle of *P. maximus* varies along the coast of Norway (Strand and Nylund 1991). In a population from the western coast (60°N) they observed spawning activity from July to September at a water temperature of 13–15°C, while a population from mid Norway (64°N) showed a synchronised spawn in June when water temperature was 7–9°C. Strohmeier et al. (2000) observed spawning from late March until September in the western population (60°N). In the northern population the gonad recovery was initiated in August when the temperature was at maximum, and was followed by a rapid increase in the gonadosomatic index through the autumn (Strand and Nylund 1991). In the southern population rebuilding of the gonad was found from October–December (Strand and Nylund 1991; Strohmeier et al. 2000). Strohmeier et al. (2000) studied the seasonal variations in chemical composition of the gonad and storage organs in *P. maximus* and suggests that switches in energy allocation divide the season in two parts in scallops from western Norway: (1) a period of reproductive growth from October to June and (2) a period of somatic growth and storage from June to October.

Scallops transferred from the northern population to be used as broodstock at the hatchery outside Bergen (60°N) seem to maintain the reproductive cycle (T. Magnesen, pers. comm.). The difference in the reproductive cycle along the coast and their maintenance after transfer suggests that there is a genetic difference among populations. However, comparisons among these populations, using allozyme frequencies (Igland and Nævdal 1995) and restriction fragment analysis of PCR amplified mtDNA fragments (Ridgeway and Dahle 2000), show no evidence of differentiation. Ridgeway and Dahle (2000) argue that this may be explained by the high dispersal capability of the pelagic stage combined with high rate of transport in the coastal currents. They also compared the Norwegian data with data from British populations and concluded that they apparently belong to separate gene pools.

21.3.2 Fishery

Exploitation of the great scallop in Norway has primarily been impeded by the unfavourable bottom conditions for dredging. Early dredging attempts yielded low returns, due mainly to rough bottoms and an abundance of seaweed that filled the dredges in only short tows (Wiborg and Bøhle 1974). Since the 1960's, SCUBA diving has been the common harvesting method. The harvest by leisure divers has probably been extensive in some areas along the coast (Strand and Vølstad 1997). The harvest of the great scallop is not regulated, while selling scallops is regulated through licensed dealers. In the beginning of the 1990's this statutory marketing was implemented, and figures on

catch appeared (Table 21.1). Prompted by efforts on developing a shellfish industry in Norway the catches in recent years have increased up to 421 t with a value of 8.3 million NOK in 1999 (Table 21.1), when 40–50 divers were registered by the Regional fishermen's sales organisations in mid Norway. A diver may catch 150–250 kg scallops per day (3–4 scallops per kg), 3–5 days a week (T. Strohmeier, pers. comm.). The possibility of over-exploitation of the harvestable stock has been an issue also among many harvesters, particularly in relation to the possibilities of stock enhancement through cultivation. The increase of divers participating in this fishery in 2000, has led the Norwegian Labour Inspection Authority to observe the requirements on diver certification for scallop harvesters in the main harvesting areas. This has reduced the number of diver-fishermen and consequently the supply of scallops to the markets.

21.3.3 Aquaculture

Spurred by the increasing European scallop cultivation interest in the 1980's, the feasibility of commercial culture of *P. maximus* in Norway was considered. Extensive areas along the coast might provide suitable habitat, and growth studies from western Norway suggested that scallops attain commercial size (100 mm) in 4–5 years after spawning (Strand 1986). During the late 1980's, focus was on the development of hatchery technology and cultivation methods appropriate for Norwegian waters (see Strand and Vølstad 1997). Attempts have been made to collect spat in Norway, but results have so far been poor (Strand and Vølstad 1997; H. Skjæggestad, pers. comm.). The large-scale pilot commercial hatchery, which was built in Øygarden, north of Bergen, in 1987, was closed in 1991, mainly due to problems in scaling up the production. However, based on promising biological results the hatchery was reopened in 1993, and became a core activity in the Norwegian Scallop Programme, which was established in 1994 by farmers, regional authorities and research institutions. The initial challenge in this programme was to link the expertise in the research sector with the private interests and experience in shellfish farming. The participants consisted of many small enterprises, which alone were not able to make the required financial contribution to the development. In 1996 the hatchery was taken over by a private company where 40 participants in the programme became shareholders. The programme was extended and embraced all research and industry development activities on scallop farming. The main activities were to develop and distribute knowledge and expertise, develop networks, to co-ordinate the activities and in collaboration with the governmental authorities to adjust regulations allowing this development activity in the coastal zone. In 1995 the Directorate of Fisheries issued a regulation to obtain a license for intermediate culture trials at up to 10 sites granted for 15 months. This regulation was extended in 1997 to include license for seabed culture trials at three sites granted for 5 years. Attraction of larger investment to the shellfish industry development was another goal in the programme, and this was realised in 1997–1998 when several companies together with governmental funding made assets in scallop farming development. Still, a long term and extensive effort to develop this industry is required. In 2000, the parliament forwarded a law proposal regulating sea-

ranching of sedentary species, whereby a statutory right will be implemented allowing the recapture of released individuals.

The developments of scallop cultivation in Norway focus on spat production in intensive hatchery and nursery, intermediate hanging culture in sea and finally seabed culture for growth to market size. Faced with the high costs of farming scallops in suspended culture, seabed culture is considered to have a greater potential for commercial development (Strand and Mortensen 1995). At present there is one hatchery in Norway. The production of postlarvae (2 mm) in the hatchery has steadily increased from 1 million in 1993 to 15 million in 1999, and since 1997 the production of 15 mm spat have stabilised at about 2 million spat (Fig. 21.2) (Magnesen 2000). Production capacity is now largely forced by demand from farmers. Development of methods and technology have significantly improved the efficiency of scallop spat production in the hatchery. In particular, during 1998 and 1999 a better efficiency was obtained in all stages up to postlarvae, and in 1999 a better strategy for broodstock conditioning provided that only half the number of broodstock was needed, compared to previous years, to produce the 2.4 billion eggs (Fig. 21.2) (Magnesen 2000). The spat originates from broodstock collected from populations in Hordaland and Trøndelag, in order to supply local stock for the main seeding areas. Scallops from these areas have a different reproductive cycle (Strand and Nylund 1991) and stock-specific conditioning regimes have been established (Magnesen et al. 1999). Broodstock conditioned at 12–13°C and fed flagellates and diatoms at a 1:1 mixture for up to sixteen weeks are spawned from December to June. The problem of low larvae survival during February–April in previous years has been resolved by improved conditioning in 2000 (T. Magnesen, pers. comm.). This has significantly increased the production efficiency of spat for optimal transfer to nurseries and further growth before the first winter. Andersen and Ringvold (2000) indicated that broodstock diets richer in the Tahitian *Isochrysis galbana* improves larval yield during spring-summer, while diets richer in diatoms may result in higher larval yield in winter. Duinker et al. (1999) exposed adult scallops to simulated natural (decreasing), constant and increasing photoperiods and results showing significantly higher gonad indexes and larger oocyte diameters in scallops given the latter two photoperiod regimes suggests that photoperiod affects early rebuilding of gonads in scallops from western Norway.

In the hatchery, larvae grow at 18°C to settlement in 3–4 weeks, and postlarvae grow to 2 mm size in 6–8 weeks (Magnesen 2000). Since 1996 there have been occasional high mortalities of larvae, suspected to have a bacterial aetiology. Since the use of the antibacterial agent chloramphenicol is not accepted in a commercial industry, considerable effort was made to find alternative agents or prophylactic methods to solve the bacterial problem. The minimum inhibitory concentrations for several antibacterial agents have been studied to develop optimal therapeutic procedures (Torkildsen et al. 2000), but large scale trials of alternative antibacterial agents have so far not been successful (L. Torkildsen and Ø. Bergh, pers. comm.). Studies on the potential use of probiotic bacterial strains show promising results (L. Torkildsen and Ø. Bergh, pers. comm.), but this concept is still prospective. The use of flow-through systems for the larvae culture is promising since bacterial numbers are low and survival of larvae is

Figure 21.2. Hatchery production of *Pecten maximus*; egg, larvae, postlarvae (2 mm) and spat (15 mm) during 1993–1999 (from Magnesen 2000).

acceptable (Andersen et al. 2000; Magnesen 2000), but further studies have shown significant seasonal variation (T. Magnesen, pers. comm.). Andersen et al. (2000) also suggest that large flow-through silos (developed for rearing fish larvae) should be further developed with the aim of avoiding prophylactic use of antibacterial agents.

The first transfers of postlarvae (2 mm) from the hatchery to nursery in the sea during early spring resulted in high mortality, and hindered the extension of seasonal deployments, which is needed for scaling up the production. High survival rates (20–50%) of postlarvae (2 mm) to a saleable spat of 15 mm were obtained only by transferring

spat after the seawater temperature increased to 8°C in May–June (Christophersen and Magnesen 1996). For larger spat (>4 mm) high survival rates were obtained at temperatures higher than 6–7°C. Between 1995 and 1997, a traditional Norwegian oyster poll (landlocked marine basin) (Strand 1996) was used as a water source for a landbased nursery. The temperature of the basin water can reach 10°C by April, facilitating an early transfer of postlarvae from the hatchery, and providing efficient predator control and high survival compared to the culture in sea conditions (Christophersen and Magnesen 1996). However, during the summer of 1997 scallop spat suffered high mortality. The scallops were heavily infested with tube dwelling polychaetes (*Polydora* sp.) which were considered the main cause for this mortality (Mortensen et al. 2000). In total, approximately one million spat — representing one third of Norway's intensive scallop spat production in 1997, was lost and scallop cultivation at this site was terminated. Transfer of the postlarvae to the sea in June–July has so far proved to be the most reliable method for grow-out to a saleable size. At present postlarvae are also transferred to a landbased nursery using outdoor tanks and recycling of heated water, from February and onwards (Magnesen 2000).

Scallop spat produced in hatcheries for continued on-growing normally require transportation between sites, and the associated stresses may cause mortalities. This situation has been particularly apparent in Norway since spat have originated from only one hatchery, and only a few nurseries and on-growing locations are found along much of the southwestern coastline (Brynjelsen and Strand 1996). While transport methods have been established, there is a need to assess the impact of transport on subsequent survival and growth, and to develop methods to assess the vitality of spat in advance of transfer. Christophersen (2000) investigated the effects of simulated transport (i.e., spat held in coffee filters at a temperature of 10°C) between hatchery and nursery on survival and growth of scallop spat of 2 mm size. To ensure high survival and growth rates, transportation is recommended to last no more than 12 h, which is within the travelling time commonly practised in Norway. Christophersen (2000) states that transportation up to 24 h may be recommended when spat in good condition are transferred to favourable environments, if these variables are known. Based on the need to develop simple methods to assess the vitality in advance of transfer, Minchin et al. (2000) studied the effects of air exposure on the righting and movement behaviour of scallops and related this to subsequent survival. As for scallop spat of 2 mm size (Christophersen 2000), Minchin et al. (2000) suggested that emersed transfer of juvenile scallops lasting more than 12 h should be avoided. Scallops emersed for 18–24 h showed subsequent (10 days) mortality that was 10–30%. They also showed that scallops did not show significantly different behaviour whether they were emersed upright or inverted. However, chilling (<10°C) during transport may prolong scallop vitality. It was demonstrated that at temperatures >9°C, behavioural responses like measures of movement and righting, may be a simple and effective method to assess vitality which can assist in the management of scallop culture.

Intermediate culture trials have been carried out along the western coast (59–65°N) by farmers participating in the Norwegian Scallop Programme aiming at farmer training and increased understanding of criteria for site selection along the coast. Scallops

cultured at selected locations grow from 15–20 mm to 45–55 mm in one year (Strand and Mortensen 1995; Brynjelsen and Strand 1996). During summer growth is favourable in shallow depths (5–10 m) to depths below 15 m (Lund 1991; Brynjelsen and Strand 1996), while survival during winter is generally higher below 15 m (Brynjelsen and Strand 1996). During the winter of 1996, scallops suffered high mortalities at many sites. At all sites where minimum temperature was below 2°C, scallops experienced total mortality (Brynjelsen and Strand 1996). For acceptable levels of survival, temperatures above 4°C are required. The sites where scallops had total mortality were all located in the southernmost (Rogaland) and northernmost (Trøndelag) regions, and historical temperature data from the critical northern coastal areas have been used in identifying areas of high risk for scallop cultivation. Subsequent experiments showed that survival and behaviour were significantly affected by temperature differences between 3°C and 2°C (Strand, unpublished data).

Large variations in seawater parameters occur in Norwegian coastal areas. Temperature and salinity variations are caused by variations in fresh water supply and meteorological conditions, but may be exceeded by seasonal variations. The tolerance to reduced salinity in scallops is highly temperature dependent (Strand et al. 1993), and at 5°C a high mortality of scallops occurs at salinities lower than 26‰. Strand et al. (1993) recommended that scallop farms in western Norway should be located in areas where salinity seldom drops below 29 ppt. Also filtration rate and behaviour of the scallops were severely affected by lowering the temperature from 9°C to 5°C (Strand et al. 1993). Along the southwestern coast, upwelling may rapidly develop during summer after the onset of northwesterly winds (Sætre et al. 1988). Chauvaud and Strand (1999) demonstrated that such upwelling events succeeded by a small drop in temperature, from 8°C to 6°C, negatively affected the shell growth of scallops; up to a 50% decrease in daily growth rate.

Motivated by the use of landlocked marine basins for extensive marine fish larvae culture in Norway, Andersen and Naas (1992) compared growth of juvenile scallops in a basin loaded with fertilisers with growth at two locations at sea: one being potentially loaded with organic materials from a fish farm, and the other an unloaded site. The results indicated that fertilised basins are not useful locations for farming scallops unless the temperature, and phytoplankton density and composition are carefully controlled. Reitan (2000) showed that scallop spat held in a landlocked marine basin enhanced by artificial fertiliser attained a bigger size than scallops held outside the basin at an unfertilised site, but growth of scallops in this experiment was inferior to what could be expected in selected locations for scallop farming along the coast (Lund 1991; Strand and Mortensen 1995; Brynjelsen and Strand 1996).

Releases of scallops on to the seabed for cultivation during the mid 1990's revealed heavy predation from the brown crab *Cancer pagurus*, and this has been a major impediment to the development of scallop seabed cultivation in Norway. Seeding trials during autumn showed extensive attraction of crabs to the sites, and high mortality was shown for scallops up to about 50–60 mm shell height (Strand et al. 1998). This immense and unacceptable level of crab predation on some of the first seeded scallops prompted an interest from the industry to develop fences in order to prevent the crab from accessing the

scallops (Strand et al. 1999). Plates of steel (0.6 mm) coated by PVC, with a smooth surface, erected 30 cm height above the sediment and dug 20 cm into the sediment are now used by farmers to prevent the brown crab access to fenced scallops. Further technical improvements and biological assessments are being made to consider the economical viability of fenced scallop cultivation on the seabed. Other strategies now being considered are scaling up the number of scallops released to the seabed, seeding at low densities and active predator control.

Predation experiments have shown that the crab *C. pagurus* prefer cultivated scallops to wild scallops (Haugum et al. 1999). This is probably due to weaker shells in cultivated scallops. Shell strength increase with scallop size, but wild scallops were twice as strong as cultivated scallops. A better knowledge on the variation in shell strength of scallops and the determinant factors affecting the mechanical structure of scallops shells are assumed to be of major importance for the development of scallop seabed cultivation in Norway.

Co-location or duo-culture of Atlantic salmon and scallops is being considered in Norway in order to benefit from higher efficiency on labour, production facilities, management and even biological production (i.e., sustainable integrated aquaculture). Bivalve harvest through cultivation is also argued to balance the nutrient input to the marine environment from fish farming (Reitan 2000), and concepts are launched of using energy from the petroleum industry, as heated water and bioprotein, in an integrated system for marine aquaculture including bivalves (Åsgård et al. 1999; Jacobsen 1999). However, at present the distance between aquaculture sites is regulated to be at least one kilometre, which is a preventive measure to avoid disease transmission between bivalves and fish (e.g., Atlantic salmon). Laboratory tank cohabitation experiments of Atlantic salmon (*Salmo salar*) with scallops *P. maximus* challenged with the bacterium *Aeromonas salmonicida*, causing the disease furunculosis in salmonid fish species, showed that furunculosis was transmitted to susceptible salmon via the scallops (Bjørshol et al. 1999). Studies of the fate of the fish pathogenic infectious pancreatic necrosis virus (IPNV) in scallops (Mortensen et al. 1992; Mortensen 1993a) showed that bivalves probably should be considered potential vectors of fish pathogenic viruses. These studies have been guidelines in the management of production and movements of cultured bivalves and fish in coastal areas of Norway (Mortensen 2000). Nordtug et al., (1999) showed in a field study of scallop cohabitation with salmon that scallop growth and survival was not affected, and laboratory tests with adequate medical and chemical substances used in fish farming indicated only an acute negative effect in the very close vicinity of the salmon farm.

A restricted health survey on selected stocks of *P. maximus* has been performed in Norway since 1989 (Mortensen 1993b). To date, no serious infectious diseases or parasites have been detected (Mortensen, pers. comm.). There is a high priority on bivalve disease research and management in order to protect the industry from disease introductions (Mortensen 2000).

21.4 AEQUIPECTEN OPERCULARIS

The queen scallop *A. opercularis* has almost the same distribution as *P. maximus*. It is found from the Lofoten Islands (69°N) in northern Norway, the Faroes and south to the Danish Sound (56°N) (Figure 21.1) (Ursin 1956; Broom 1976; Høysæter 1986). In the Faroes it is found on sandy, rocky or soft bottom from 50 to more than 100 m depth, being most abundant around 100 m (Ursin 1956, Nicolajsen 1997). In Skagerak-Kattegat queen scallops are generally found on fine sand and gravel from 20 m down to 100 m. *A. opercularis* prefer flowing water, salinities higher than 25‰ and temperatures in the range of 3–16°C. These requirements are thought to determine their distribution pattern in this area (Ursin 1956).

On the west coast of Denmark mudflats dominate the coastline. Queen scallops are rather scarce in this area since it appears that *A. opercularis* avoids soft bottoms. High numbers of *A. opercularis* are found between Doggers Bank and the coast of northern England and Scotland (Broom 1976).

In Scandinavian waters there is probably one spawning period per year, and it lasts from June (Faroes) to October (Skagerak-Kattegat) (Ursin 1956). Seasonal growth rates are not well documented from this area. Ursin (1956) found that *A. opercularis* from Danish and Faroese waters grows rapidly early in life, 40 mm in 2 years, after which growth slows reaching about 60 mm in 4 years, and ceases finally after about 6 years at a length of 70 mm. The density and distribution varies from time to time and unfortunately there exists no actual estimates of densities. The most dense populations are found in the southern Kattegat, in the Sound and around the Faroes.

In the past, *A. opercularis* have been locally fished in small amounts (27 t, 1954) in the Danish sound and in Faroese waters (Ursin 1956; Broom 1976). Since 1970 a small but stable commercial fishery for queen scallop in the Faroes has developed with an average catch of about 500 t, 2,000 t and 3,000–4,000 t per year during the 1970's, 1980's and 1990's, respectively (Table 21.1). In recent years the catches have increased to more than 5,000 t per year. Until 1988 the fishing fleet comprised from 2 to 9 ships (Nicolajsen 1997). After 1988, only one boat has been dredging on the main traditional beds 1–15 nmi. from the eastern coast. The catch season is from August to February, and the fishery uses two 12-foot modified Scottish type dredges. The fishery is managed by licence and bounded catch-reporting by logbooks. A large factory trawler, originally built for a Faroes company for the Iceland scallop fishery in the Barents Sea in 1987–1989, was allowed to fish queen scallop beds north from the Faroes. This fishery was closed in 1991 (Nicolajsen 1997). Before 1990, almost all the production went to US markets. At present the main market is France. Exploratory fishing for queen scallops in southwestern Norway in 1998–1999, using dredges from the fishery in Shetland islands, has been unsuccessful (E. Aarseth, pers. comm.).

At present, there are no attempts at trying to cultivate *A. opercularis*. Some trials have been made to collect spat and grow them in suspended culture in Norway with some success, but no real effort has been made. Growth studies in pearl nets suspended at 5-m depth-intervals from 5 to 25 m at locations along a gradient from protected fjords to exposed coastal areas were performed during May to September (Lund 1990).

Temperature rather than food quantity, measured as chlorophyll, POM and POM/PIM ratio, was the most important factor explaining variation in growth of soft parts and shell. Production of *A. opercularis* in suspended nets was higher in shallow depths than deeper, while there were no differences between the locations. In Denmark and Sweden the hydrographical conditions, influenced by brackish water, restrict the distribution of *A. opercularis*. *A. opercularis* would be more suitable for aquaculture development in the Norway and the Faroes islands.

ACKNOWLEDGMENTS

We would like to thank J. Bates, Ø. Bergh, R. A. Chandler, J. Cleghorn, M. J. Dadswell, J. J. Engelstoft, S. E. Fevolden, T. Magnesen, S. Mortensen, K. S. Naidu, A. Nicolajsen, S. A. Pedersen, E. M. Rödström, G. G. Thorarinsdóttir, T. R. Waller, D. Warren, and E. Aarseth for their assistance in the preparation of this chapter.

Chapter 22

Japan

Yoshinobu Kosaka and Hiroshi Ito

22.1 INTRODUCTION

The scallop industry supports Japan's coastal fisheries and cultures with an annual increase in economic activity in shellfish producing communities (Fig. 22.1, Table 22.1). In 2000, the gross fisheries production of Japan totalled 6,384,100 metric tons (mt) and 1,875,290 million yen; these statistics include coastal fisheries of 1,576,140 mt (576,449 million yen) and marine cultures of 1,230,783 mt (527,230 million yen). Molluscan shellfisheries were 838,450 mt (127,214 million yen), which was 13.1% (6.8%) of gross fisheries production, and various shellfish, such as scallop, oyster, short neck clam, surf clam, abalone and ark shell were utilised. Japanese scallop landings reached 514,989 mt (84,146 million yen), which was 61.4% (66.1%) of the molluscan shellfisheries production. The scallop was found to be the most valuable, with the oyster coming second; the oyster landing being 37,950 million yen in value and 221,252 mt in weight. The pearl oyster produces a gem, and its culture has become a big industry; however, it is separated from the shellfish fisheries statistics.

'Yoshoku', possessive culture in the demarcated sea, is held by the demarcated fishery, its produce contributing to the stabilisation of the supply of good quality seafood. 'Yoshoku' areas are separated by caging or fencing from the common sea or culture facilities that may be set up in these areas. Scallop hanging culture, belonging to this culture category, is a high activity in northern Japan. Concerning the other culture system, 'zoshoku' or 'saibai', sea farming or marine ranching is a project in the common sea by the right of the common fishery. 'Zoshoku' areas are designed by a consensus in the common sea. 'Zoshoku' has been conducted recently at every stage from feasibility studies to economic enterprises on the marine species of fish and shellfish. Of the seeds released for sea farming in Japan, the largest numbers are scallops (Table 22.2). The scallop industry is said to be the honour student of sea farming in Japan. The high industrial activity of the Japanese scallop currently leads all other developing mariculture efforts.

Two scallop species, Japanese and Bay, *Patinopecten (Mizuhopecten) yessoensis* (Jay, 1857) and *Pecten (Notovola) albicans* (Schröeter, 1802), have mariculture potential. Even so, there are several other species of scallops, which are also utilised for food in Japan, e.g., Noble or 'Hiougi-gai', *Chlamys (Mimachlamys) nobilis* (Reeve, 1852); Swift's or 'Ezokinchaku-gai', *C. (Swiftopecten) swiftii* (Bernardi, 1858); Farrer's or 'Azumanishiki-gai', *C. (Azumapecten) farreri* (Jones et Preston, 1904); and Japanese Moon or 'Tsukihi-gai', *Amusium japonicum* (Gmelin, 1791).

Cultures of Noble and Farrer's scallops have been attempted, though for these production levels remain low. In this paper, the mariculture and fisheries of Japanese, Bay and Noble scallops are described.

22.2 PATINOPECTEN (MIZUHOPECTEN) YESSOENSIS

The Japanese scallop, *Patinopecten (Mizuhopecten) yessoensis* Jay, is called 'Hotategai' in Japanese and has other names such as Japanese Common, Yesso or Giant Ezo scallop (Fig. 22.2). Jay (1856) obtained the Japanese scallop specimen from Hakodate of south Hokkaido, northern Japan, and reported it as *Pecten yessoensis* n. sp. Dall (1898) called *Patinopecten*, as one section of *Pecten*, and Arnold (1906) separated it as a subgenus. Masuda (1963) called the subgenus *Mizuhopecten* separating it from *Patinopecten* and Habe (1977) adopted this subgenus name.

22.2.1 Biology

The Japanese scallop is a cold water species distributed in the coastal areas of the sub arctic zones such as the North Pacific Ocean, the south Okhotsk Sea, the Japan Sea, and along the coasts of the Kurile Islands, Sakhalin, Hokkaido, and northern Honshu and North Korea. The southern limit of the natural distribution in Japan is Toyama Bay on the Japan Sea coast and Tokyo Bay on the Pacific Ocean coast (Fig. 22.3). The main mariculture areas are Hokkaido, north Honshu, north Japan, and some of the surrounding areas, which change seasonally. These coasts are influenced alternately by both warm currents in summer and cold ones in winter alternately from year to year (Fig. 22.4). Aberrant water masses also (Komaki 1975; Fujii and Sato 1977) appear in each season (Fig. 22.5).

Shell valves are loosely shut together, the right valve being larger than the left one. The shell shapes are slightly convex in the right valve with a yellow-white surface. In the left valve the shapes are either quite flat or slightly convex with a purplish brown surface or an occasionally with an orange yellow surface. Both interiors of the valves are white. The anterior ear and the posterior one have symmetrical beaks at both sides of umbones and make hinge-margins straight; however, the right valve has a shallow byssal notch below the front ear. Hinges are united by a narrow ligament. Valves are ornamented with radiating ribs of between 15 and 32 ribs on the right and 13 to 31 on the left. It has been found that the number of ribs varies geographically and is maintained hereditarily (Kinoshita 1935b). The number of ribs of a scallop in Mutsu Bay and from the northern part of Iwate Prefecture is between 19 and 22 on the left valve, 18 and 21 on the right. The number in Japan Sea, Hokkaido and the Okhotsk Sea is between 23 and 24 on the left valve, 22 and 23 on the right. The number in Funka Bay is between that of the numbers in Mutsu bay and in the Okhotsk Sea (Kawamata 2002).

The life cycle begins when the demersal eggs are fertilised in the sea after spawning (Fig. 22.6). Fertilised eggs start cleavage and reach the subsequent development of the trochophore at four days. The early veliger larva stage with a fully formed prodissoconch shell, (D-larva) is reached 5–7 days after fertilisation. The umbones of the late veliger larvae are fully-grown and overhang the straight hinge by 30–35 days. This pediveliger attaches to the substratum with byssal threads by 40 days. Immediately after settlement, rapid changes in the shell morphology of the dissoconch (spat shell) and growth of internal organs take place, leading to the adult scallop form.

Figure 22.2. A: *Patinopecten (Mizuhopecten) yessoensis* (Jay, 1857). B: *Chlamys (Azumapecten) farreri* (Jones et Preston, 1904). C: *Pecten (Notovola) albicans* (Schröeter, 1802). D: *Chlamys (Swiftopecten) swiftii* (Bernardi, 1858).

Figure 22.3. Main mariculture areas in Japan and the natural distribution in East Asia of the Japanese scallop, *Patinopecten (Mizuhopecten) yessoensis* Jay.

Figure 22.4. Main currents around Hokkaido and north Honshu in summer and winter.

Figure 22.5. Water masses around Hokkaido and northern Honshu at each season. A: Tsushima warm current, B: Tsugaru warm current, C: Soya warm current, D: Northward current of Kuroshio, E: Coastal branch off the Oyashio (Kuril cold current), F: Offshore branch off the Oyashio (Kuril cold current), G: East Sakhalin cold current, H: Liman cold current, I: West Sakhalin coastal water, J: Cold water west off the Tsugaru Straits, K: Cold water west off Thugaru Straits, K: Cold water west off Musashi-tai, L: Inter-cool water, M: Mixed water areas of circulating current, N: Floating ice area, O: Coastal water area (after Komaki 1975; Fujii and Sato 1977).

After being attached for 4–5 months, the spat grows to approximately one centimetre (cm) shell length, starts to fall off the substratum and the free spat inhabits the sea bottom. The bottom dwelling spat grows into a juvenile of 2–5 cm shell length by the next spring. The scallop grows to 5–9 cm shell length and 16–80 g body weight at two years old, 8–12 cm and 60–170 g at three years old, 10–15 cm and 110–300 g at four years old, and then larger with a reduction in growth rate as it grows older. Some scallops reach 20 cm and 1 kg at more than ten years old.

Figure 22.6. Life cycle of Japanese scallop, *Patinopecten (Mizuhopecten) yessoensis* Jay, with a note on the culture process. (modification from Yamamoto 1964; Maru 1972, 1976, 1978; Kawamata et al. 1981; Kosaka et al. 1997).

The scallops dig shallow depressions on the sandy bottom, feeding on phytoplankton and detritus collected. The feeding and growth of scallop are obstructed when the flow surpasses 20 cm s^{-1} (Miyazono 2000).

The optimum temperature for feeding is within the range of 5–20°C. The lower and upper limits are 4 and 22–23°C, respectively. The optimum temperature for their maximal growth is between 10 and 15°C (Yamamoto 1964). A spat is capable of growing at even 25°C though the upper lethal temperature of a 1-year-old scallop is 22–23°C (Maru 1985; Kosaka 1996).

An energy flow diagram for scallop, *Patinopecten (Mizuhopecten) yessoensis* (Jay), in Mutsu Bay, has been outlined as follows. About 20–30% of energy is voided as egesta, while most of the rest is assimilated. About 50% (1-year-old scallops) to 70% (3-year-old scallops) of assimilated energy is lost to the surroundings as heat (respiration). The net growth efficiency ranged from 50% (1-year-old scallops) to 29% (3-year-old scallops). The ratio of energy for the development of gonad tissue to the energy assimilated is about 2% in one-year-old scallops to 12% in 3-year-old ones (Fuji et al. 1974). Assimilation efficiency was high from May to July and low from November to January (Kurata et al. 1991). Oxygen consumption increased with temperature, excluding April–May when a water temperature was 0–18°C. On the other hand, oxygen consumption decreases when the water temperature is higher than 18°C (Kurata 1996a).

Juveniles differentiate sexually after little over one year (about 15 months). This scallop is gonochoristic. When mature, the gonad of the female scallop turns reddish orange in colour and that of the male turns pale yellow. Fecundity varies with age, but is usually in the range of 8 to 18×10^7 eggs per female (Yamamoto 1943). Previously, the scallop matured at more than two years old (Wakui and Obara 1967; Maru 1978a; Osanai et al. 1980; Kawamata, Tamaoki and Fuji 1981). Recently, the sexual maturation or differentiation begins at one-year-old and spermatozoa and so ovaries of one-year-old scallops are spawned from mid February to late April (Kosaka et al. 1996a). Hermaphroditic scallops are rarely found (Yamamoto 1964; Maru 1978b). In Saroma Lake the gonad develops from autumn to winter, becoming mature by May, with the spawning occurring from May to June (Maru 1976, 1985). In Funka Bay the gonads mature from March to April and spawning occurs from May to June (Kawamata 1981, 1983). In the Japan Sea coast of Hokkaido scallop become mature from March to April and spawn from April to May (Kawamata 1988). The gonads of scallop in Mutsu Bay develop from October to February, mature from January to February and the gametes were spawned from February to June (Kosaka et al. 1996b, 1997a).

The temperature in spawning season is 7–12°C in Saroma Lake, 4–12°C in Funka Bay, 6–10°C in Mutsu Bay and 8–12°C in Toni Bay, Iwate (Maru 1976; Kawamata 1983; Kosaka et al. 1997a; Mori 1975).

22.2.2 Fishery

The scallop had been the main important export item to China in the mid-Tokugawa period (Tokugawa jidai 1600–1868) of Japan (Thubata 1982). At that time the scallop was fished by a hand trawl or 'Teguri-ami' in Mutsu Bay, and was landed mainly in the

regions of Hiranai and Kominato, Aomori. The fishery around the east Hokkaido coasts, facing the Okhotsk Sea was started in the late 1800's (Ito 1964). Use of the powered trawl or 'Gangara-biki' the scraper, scallop dredge, otherwise known as 'Hotategai-keta-ami', was extended in the 1940's because of a food production increase and a labour force decrease during the World War II. Catch statistics are available from the late 1800's for Mutsu Bay and the early 1900's for Hokkaido.

Until 1968, the scallop fishery had been dependent on natural resources. At that time fishing efforts concentrated on the high density populations which appeared by excellent natural recruitment of a year class. Scallop fishing for these resources would cease within 2–3 years because populations were completely exhausted. This was a normal fishing style for the natural resources. There was almost no regulation except the simple control of the shell size and the fishing period. Thus, catch statistics fluctuated in relation to the natural biomass changes (Fig. 22.7).

The history of the Japanese scallop fishery from 1910–1987 is classified into six periods as follows (modified from Tanaka 1963; Kanno and Wakui 1978; Thubata 1982): (1) 1910–1923: temporally high catch period, annual catch fluctuated with one peak of high landing in 1915, annual average catch was 16,000 mt; (2) 1924–1932: stable high level catch period, annual average catch was 37,000 mt; (3) 1933–1944: extreme high catch period, average was 43,000 mt; (4) 1945–1968: stable low level catch period, catch levelled down to average of 11,000 mt without peak; (5) 1969–1976: hanging culture development period, hanging culture production rapidly increased, average of 57,000 mt (Fig. 22.8); (6) 1977–1996: sowing and hanging culture mass production period, the production passed 100,000 mt mark in 1977 and 200,000 mt mark in 1983, 400,000 mt mark in 1992, and then it got to over 500,000 mt in 1995 at last. (7) 1997–2000: More than 500,000 mt is being produced steadily after 1997. The scallop industry in Japan develops into a mass production epoch.

Hokkaido has yielded a major catch in from times of old to date. The scallops caught around Hokkaido represented 77% of cumulative scallop landings in Japan during the period 1910–2000 (Table 22.1). The sowing culture and wild production from the sea bottom around Hokkaido has contributed 50% to the total amounts in Japan, 1981–2000. This especially so in 2000 when the production of sowing culture and wild production in the Okhotsk Sea came to occupy 53% of the total amounts in Japan (Fig. 22.9, Table 22.3). The mass mortality that happened in 1975–1977 in Mutsu Bay, Aomori and in 1977–1980 in Funka Bay, Hokkaido, resulted in the hanging culture production immediately decreasing in the late 1970's (Kanno et al. 1980). After that the hanging culture production has been extended smoothly and reached its highest level, 265,553 mt in 1995. However, production level has decreased since 1996 due to mortality and the growth defect in the Funka Bay. The hanging culture production in Funka Bay and Mutsu Bay in 2000 occupied 44% and 42% of the total harvest in Japan, respectively (Table 22.4). Thus, the Hokkaido region is the home of the Japanese scallop in Japan.

22.2.3 Culture

Scallop mariculture developed rapidly due to the technical invention of successful methods for natural spat collection and the intermediate culture in embayment seas in the mid-1960's after 30 years of investigative trials. Scallop spat collection in Japan was first attempted with successful results at an experimental stage in Saroma Lake in 1934 (Kinoshita 1935a). Industrial results of the spat collection fluctuated greatly because the technical methods were still undeveloped. After many experiments, a successful spat collector was invented in 1964, by Mr. Toyosaku Kudo, a fisherman in Mutsu Bay, at Aomori Prefecture (Yamamoto et al. 1971; Tsubata 1982). The scallop collector is a double structure and is composed of a mesh bag filled with substratum. The result of the use of this type of collector has been that in embayment seas relatively stable spat collection has been achieved. After the mid-1970's, offshore spat collection in open sea coastal areas was developed because of a lack of seed for sowing (Ito 1984).

The spat are caged for seed production by a long line system for several months. The caged culture for seed production is called "chukan-ikusei" or intermediate culture. The intermediate cultured seed are used for both hanging culture in exclusive sea areas and sowing on prepared sea bottoms.

Scallops in hanging culture grow more rapidly than in sowing culture (Fig. 22.10). The weight of a 2-year-old scallop grown by hanging culture has the same weight as that of a 3-year-old scallop grown by sowing culture in Mutsu Bay, and the weight of a 2.5 years old scallop grown by hanging culture in Saroma Lake is the same as a 4.5-year-old scallop grown by sowing culture in the Okhotsk Sea. In addition, the growth of scallop in hanging culture is greatly different between Saroma Lake and Mutsu Bay. The scallops in hanging culture in Saroma Lake grow to only about 90 g in 2 years, though ones in Mutsu Bay grow to over 120 g in 2 years. This difference is caused by differences in the environment, the culture technique, the culture density and the food supply.

22.2.4 Seed Production

Recently all scallop seed has been produced from a natural spat collection. Until the natural seed production became a mass production stage, the artificial seed production in land tanks had been examined by the mid-1970's (Kinoshita et al. 1943; Yamamoto and Nishioka 1943; Tanaka et al. 1977; Tsubata 1982).

The mass and cost of natural seeds gain an advantage of those of artificial seeds. Seed production takes the sequential process from spat collection to intermediate culture.

22.2.5 Spat Collection

A process of spat collection and its research is as follows (Ito 1986; Ito et al. 1988a; Aoyama 1989): (1) check the spawning: to estimate the timing of spawning use changes in the gonad index, weight ratio of gonad to soft body; (2) search for the larvae: determine the set timing and location of spat collectors by larval monitoring; (3) set the collectors: collectors are set where the larvae are common; (4) check the attached spat: count spat

Figure 22.10. Growth curves of Japanese scallop, *Patinopecten* (*Mizuhopecten*) *yessoensis* Jay, in hanging culture and sowing culture (modification from Aoyama 1989; Sato 1993; Nishihama 1994).

and measure shell size to determine the intermediate culture management planning and timing. Although this process has been directly derived from the spat collection data, other information supports it as well (Ito and Hamaoka 1988b).

Since the 1970's, surveys and research have been carried out with the objective of providing forecasts of available spat collection in Mutsu Bay. Every year from December to July, studies are conducted on the gonad index of broodstock, on larval density, spat, and environmental conditions, using automatic monitoring buoy robots (Aoyama 1989). In the Okhotsk and Japan Seas, Hokkaido, studies on gonad index of broodstock, the larval density, the spat, and temperature are done from April to September (Kurata 2001) and similar studies are done in Funka Bay, Iwate and Miyagi annually.

More than 10,000 spat per collector can now be collected consistently in Mutsu Bay. In strong years, more than 100,000 spat can be collected on average, the record catch being more than 1,000,000 spat in one collector. Because, the production of spat fluctuates in Funka Bay greatly (Table 22.5); spat are imported from the Okhotsk Sea or the Japan Sea, Hokkaido (Fig. 22.11; Kurata et al. 2001). Juvenile seeds of six months to one-year-old are imported from the Japan Sea or other regions and then released in the Okhotsk Sea and the Nemuro Strait. The annual volume of sales of seed reaches more than 2 billion individuals in Hokkaido.

Collectors for natural spat collection vary with conditions and purposes as follows (Fig. 22.12).

The collectors being used in Saroma Lake and Noto Lake are made of Netron, with a large mesh size, which is loosely stuffed into the outer net of a netron bag. The mesh size of the outer net is 5 mm, larger than the mesh size of an onion bag. Worn-out salmon and trout gill nets are sometimes used as substratum.

Worn-out salmon and trout gill net, or netron is being used as substratum in Mutsu Bay. Though the onion bag of 1×5-mm mesh size is commonly used for outer nets, bags of 1×1-mm, 1×2-mm and 2×2-mm mesh sizes are also used. It varies due to the conditions, or the preference of the fisherman.

Figure 22.12. Facilities for spat collection for Japanese scallop, *Patinopecten* (*Mizuhopecten*) *yessoensis* Jay.

Juvenile starfishes stick to collectors every year in Funka Bay and they grow inside the bag, and prey upon the scallop spat. Generally, the 'Straight net' style collector is being used at present as a countermeasure to this. The 'Straight net-onion bag' style collector, which is a net put over a long straight net, is also being used in Funka Bay. When the spat reach 3-4 mm in size, juvenile starfishes are removed, and the temporary seed collection or 'Karisaiyo' (spat being put in the pearl net of small mesh size) is carried out.

If the mesh size of the outer net is small, the collector becomes dirty immediately due to the mud and growth of fouling organisms. When the mesh size is too large, the spat fall off. Despite this, the larger size is favourable since the spat inside the bag grow fast. Megalopa larvae of crabs sometimes stick to collectors in the Nemuro Strait. Larvae enter the bag and metamorphose into juvenile crabs, using scallop spat inside the bag as feed.

One juvenile crab is able to eat all scallop spat in a collector. Because of that, onion bags with mesh size smaller than the size of megalopa larva are used for the outer net in the Nemuro Strait. On the other hand, in Mutsu Bay, the crustacean, *Cymodoce japonica*, called 'Nihonkotubumusi', can enter the bag, when the mesh size of the outer net is large, and eat all the scallop spat. One type of 'Nihonkotubumusi' eats 20 to 30 scallop spat everyday. If over twenty crustaceans get into the collector, all scallop spat will be eaten in a month. The collector whose mesh size is small is favourable even if the growth of spat is reduced. On the Japan Sea side of Hokkaido, the larval density is very low and it seems as though the outer net does not become dirty, and so here too an onion bag is generally used for the outer net. Therefore, the mesh size of the outer net of a collector should be determined by the specific characteristics of its deployment.

22.2.6 Intermediate Culture

The rearing of spat from the collector up to a shell length of 3–5 cm in a pearl net is called intermediate culture. Intermediate culture is conducted by the process of sorting, caging and hanging: (1) "Bunsan" or sorting: sorting large spat with a sieve. (2) 'Shuyo' or caging: caging in nets at low density. (3) 'Suika' or hanging: hanging in water. Moreover, 'Bunsan' means the changing process from spat collection to intermediate culture, i.e., the whole process from (1) to (3). The concept of "bunsan" is to change a situation to increase productivity.

The hardware for intermediate culture is 'Zabutonkago', 'Paru-netto' or pearl net (Fig. 22.13). The sections of pearl net separate into single units, net cages, with a 30 cm square floor, and it is still used commonly in Japan due to low cost and the fact that it was originally introduced from the pearl culture. The mouth of a net is stitched closed using artificial gut and is therefore slightly troublesome to handle. Ten strings of net are linearly linked together with both ends of each singular stalk rope tied through the net centre. The stalk rope in a net becomes a vertical core prop to keep the net horizontal. Sometimes it causes crowding of scallops into a net corner because of irregular slanting due to shortening of the core rope. The seed produced by the above-mentioned process is used for both hanging and sowing culture. Generally the density of spat in the net for sowing culture is higher than for hanging culture. These cultures are described below.

22.2.7 Hanging Culture

Seeds are caged or suspended for hanging culture or 'Yoshoku'. Cultivation from seed to harvest is called 'Yosei' or 'Hon-yosei'. The fouled net is exchanged for a new net and the stocking density of scallops is reduced in the process of hanging culture. If stocking densities inside a net are too high, scallops sometimes bite each other, and damage mantles. This leads to slow growth and high mortality rates (Kosaka et al. 1996). To achieve normal growth, hanging culture is carried out according to the process shown in Table 22.6. It takes about 1.5–2.5 years to raise juvenile scallops to a marketable size. This process varies with the area or method of culture.

Figure 22.13. Facilities for intermediate culture of Japanese scallop, *Patinopecten* (*Mizuhopecten*) *yessoensis* Jay.

Table 22.6

Basic process of scallop culture in Japan.

Methods for culturing vary (as follows) (Fig. 22.14): (1) The 'Mimi-zuri', or ear suspended method; a hole of 1.3–1.5 mm drilled at the front eared beak of left valve through the right valve notch or through both front ears near a byssal notch. The 'Tegusu' method was the most commonly used method preceding the ear suspended culture method. In this method two scallops are suspended by #30 artificial strings, tied at every 12–15 cm of 6 mm polyethylene rope for hanging. Within the genre of ear suspended culture, there are methods called the 'age-pin' method and 'looped' method. The 'Age-pin' method is a method to put two scallops on a rope with a plastic clip called an 'Age-pin'. Another method is called the 'loop' method and was developed recently. The loop made of plastic string is made by the interval on the rope 12–15 cm, and an artificial string is passed through the rope between loops, and two scallops are suspended between those loops by the artificial string (Fig. 22.14). One hanging contains 130 individuals per twine. This method has become the most common recently since the materials are cheap and it is easier to harvest. This makes overcrowding imminent in Funka Bay. (2) The 'Maru-kago', 'Andon-kago', or lantern net: composed of short cylindrical units 50 cm in diameter and 15 cm high and framed by #8 vinyl covered wire. Cylinders are linearly connected together. The cage is made of a polyethylene mesh of 7 'Bu' or 21 mm knots and 5 mm hanging twine. Five to ten scallops per unit are caged. (3) The 'Poketto-kago' or pocket net: 60 cm wide and 20 cm high and is constructed from double nets and #8 vinyl covered wire, stitching two face-to-face sheets of net to each other into a wallet shape. This creates thin pocket net shapes, joining 10–25 units. The mesh is 7 "bu", the same as the lantern net. Six scallops per unit slit are inserted. (4) The 'Hausu-kago' or house cage: a cylindrical plastic sub-unit of 15 cm diameter divided into 12 rooms, five or six subunits making one unit. Sometimes these units are hung together vertically. One individual is placed in each room. This cage was only used at a part of Okhotsk. (5) The 'Paru-netto' or pearl net: coarse mesh is used for growing cultures. Though generally a long line system is used for the culture facilities, the facilities being called 'set' in Funka Bay were used too, which is that several long lines are connected together and concrete-block, sandbag and super-anchor are used for the fixation, and buoys are attached to beam rope and main rope and it has the structure to be able to stand a storm.

Technical research on cultured scallops concerning cultivation care by Aoyama et al. (1982) and Ito et al. (1986) has shown (1) lower densities in both intermediate and hanging (growing) cultures keeps a higher growth rate and a lower mortality by reducing crowding effects; (2) less time sorting scallops and changing cages and cleaning all of which lessens handling shock to the scallops; (3) stabilising the long line facilities and the hung scallops which also lessens wave-induced shock to a scallop. Wave-induced shock damages the scallop mantles and leads to high mortality and slow growth (Kosaka et al. 1996c). These measures produce a stable harvest without mass mortalities.

22.2.8 Fouling

Several organisms, e.g., barnacles, sea anemone, hydrozoas, sea squirts, bryozans, mussels, other bivalves and algae settle on the nets and grow (Kurata et al. 1996b). Heavy fouling prevents the growth of scallops inside the net. Most fouling attached to the culture

net and the scallops is mussels. Because mussels often attach at a shallow depth, the settlement of mussels can be prevented when the culture facility is dropped deeper, at more than 20 m deep from April to July. The facility is then returned to its former depth after July (Hirano 1983).

Figure 22.14. Facilities for hanging culture and a variety of hanging hardware for Japanese scallop, *Patinopecten (Mizuhopecten) yessoensis*, Jay.

22.2.9 Sowing Culture

Scallop seeds were sown for investigative purposes off Okhotsk Sea coast of Hokkaido in 1937 (Kinoshita 1949). Release of spat without intermediate culture was the practise until about 1940. Natural juvenile scallops and seeds imported from Hokkaido were sown in Mutsu Bay of Aomori Prefecture, north Honshu, before 1969 (Tsubata 1982). In Mutsu Bay, some stocks were recaptured; however, almost nothing resulted in Hokkaido after many efforts for first 32 years.

After the development of the collector and hanging culture, one-year-old scallop and mass seed could be produced and intermediate culture could be carried out under the frozen lake. One-year-old seeds could also be produced in Saroma Lake from approximately 1965. Hence, more than ten million seed scallops have been released on the cultural sea bottom since 1967. Survival of the sown scallop population was observed in the Okhotsk Sea coasts of Tokoro, the Abashiri region, Sarufutsu, and the Soya region during the period from the late 1960's to the early 1970's. On the Tokoro coast, 23 million seeds of one-year-old scallops were sown on the culture bottom in 1967. The sowed scallop population at the age of two years old was estimated at the high survival rate of 54.7–98.0% in the next year (Okesaku and Tanaka 1969). The seed input number in Sarufutsu coast was 14–60 million individuals in 1971–1973. Three populations of three-year-old scallops were observed to have survival rates of 5.5–28.9% in 1973–1975 (Hayashi et al. 1976).

22.2.10 Enemy Clearance

There are many animals which prey on or compete with scallops, such as starfishes, sea urchins, octopuses, crabs and fishes. Starfishes and sea urchins are removed from the culture ground by scallop dredges prior to seed sowing. A mop dredge made of hemp ropes and a baited trap of the flat basket type is used for starfish capture in supplemental cases. Sometimes octopuses are fished by "tako-bako" (wooden pot), long line or hook with barrel in culture grounds. Other predators and competitors are left intact due to lack of suitable methods to removal them economically.

22.2.11 Seed Sowing

Seeds are sown on a prepared bottom at a density of 5–6 individuals per square meter. The density value is based on natural stock density (Kinoshita et al. 1944). The optimum stock density is about 4 individuals per square meter in the Okhotsk Sea (Kurata 1999). The maximum production per square meter in Mutsu Bay is 1,200 g; therefore, less than 6 individuals per square meter should be released to achieve normal growth until the market size of 200 g is reached (Yamamoto 1971, 1973; Aoyama 1989). For these reasons the density is regulated at this same value in most locations; however, different densities have been applied locally as a new venture.

The seeds which grow to a shell height of more than 3 cm after intermediate culture are released in Okhotsk Sea coast from late May to early June in the next year (Nishihama

1994). In Mutsu Bay, seeds after intermediate culture are released in December of the same year or the following May or April when they reach a shell length of 3–5 cm (Aoyama 1989).

Annual seed input sown in Japan reached 2,876 million individuals from 1985 to 2000, a 1.5 fold increase in fifteen years (Fig. 22.15). Annual seed input sown off Hokkaido coasts amounted to 2,834 million individuals in 2000. Most of the seeds were sown off the coasts of north and east Hokkaido. In order of quantity: Abashiri (1,444 million individuals, 48%), Soya (729 million individuals, 24%), Nemuro (423 million individuals, 14%). Also, the subtotal seed input number of 1,342 million individuals was produced with the independent intermediate culture in respective areas; however, 1,254 million individuals were introduced from other areas.

Seed sowed in Abashiri is almost self-sufficient because the brackish lakes of Saroma and Notoro are good for natural seed production. In the other districts almost all seed is produced from other areas; nevertheless, seed supply has been chronically insufficient due to recent excess demand. To fill the seed deficiency a new technology for offshore spat collection and offshore intermediate culture in open sea coasts was developed rapidly in the 1980's and the self-sufficient rate of the seed seedling rose.

Mass seeds in marketing are introduced from other areas (Fig. 22.16). The seeds for sowing culture were produced in the Japan Sea region of Hokkaido, and have been sold to Okhotsk Sea region frequently since approximately 1975. But, because spat collection was not successful in the Japan Sea region in approximately 1985, a large quantity of spat were imported from Funka Bay or the Nemuro Strait (Nishihama 1994). Recently, seeds is in imported into Okhotsk mainly from the Japan Sea region because of bad harvest of spat in Funka Bay (Fig. 22.11). The half shared seeds for sowing cultures are produced in the Rumoi, Soya and Nemuro regions. These regions face the open seas of the Japan Sea and Okhotsk Sea, and so the seed production depends on offshore spat collection. However, because the spat collection is fundamentally unstable in offshore regions, this shows that offshore seed production is as indispensable as production in embayment for sowing culture.

22.2.12 Care

Density and growth of sowed scallops are checked regularly. If problems are noted, countermeasures are taken. In the case of overcrowding leading to a low growth rate, scallops are removed from the culture area to reduce the density.

22.2.13 Recapture

The cultured population is usually recaptured for 'harvesting' at three or four years old in Sarufutsu and Notori Lake at 5-years-old. The four circle harvest system called 'Yon rinsai' is being adopted in the Okhotsk Sea: the culture grounds are divided into four areas, and seeds are released on one area, and released on another area in the next year. After three years, four-year-old scallops are recaptured on the culture ground where seeds are first released. Seeds are released again in the next year when scallops are recaptured.

Figure 22.15. Changes of annual sown seed of Japanese scallop, *Patinopecten (Mizuhopecten) yessoensis* Jay, Source: Fisheries Agency, Government of Japan and Japan Sea-Farming Association, 'Actual results of aquaculture seed production, acquisition and release (the whole country), materials edition'.

This is repeated. This system can define the position of the grounds where seeds should be released and scallops should be recaptured, and makes a premeditated harvest possible (Nishihama 1994; Kurata 1996).

Relationships between seed input and production in sowing districts are significant (Fig. 22.17). The seed input has a highly significant effect on the harvest on a large scale, such as the Soya and Abashiri regions, though no significance is estimated on a small scale, such as Kushiro, Oshima and Iburi districts. In the Soya and Abashiri regions, the catch was extremely high. This scallop stock level was high due to the wild population in Sarufutsu coast of that region (Tomita et al. 1982). No more than about ten percent of the sowing culture contributed to Sarufutsu's scallop production. Moreover, the seed sowing had been stopped in 1980–1985 because of high growth of the wild scallop population on this coast.

The recent increase in catches in the Okhotsk Sea has occurred due to amount of seeds released and the increased reproduction from released seeds that have mature and added to the reproduction stock. The reproduction effect was markedly different between locations of sowing culture ground (Kitada et al.1996). Because an operating plan and a processing shipping plan are made based on the number of seeds released and the stock investigation made by many fishing cooperatives, the development of the wild population that compose year classes different from the sowed population will obstruct the production planning in many cases (Kurata 1996).

The statistical scallop harvest record in Japan inconveniently includes production from the wild population and masks the positive effect of the seed input estimates. Thus, accurate analyses have not reached completion for lack of separate harvest data on sowing culture. Statistical analyses are the primary and important step to investigating the effects of scallop culture technology.

Figure 22.16. Changes in annual seed marketing of Japanese scallop, *Patinopecten (Mizuhopecten) yessoensis* Jay, in every region of Japan, 1970–2000. (Source: Ministry of Agriculture, Forestry and Fisheries, Government of Japan, 'Annual report of statistics of fishery and aquaculture production').

Figure 22.17. Relationship between seed input and production (wild and sowing culture) of Japanese scallop, *Patinopecten (Mizuhopecten) yessoensis* Jay, in the five main culture regions around Hokkaido. Figures of 1985–2000 are years of catch. Seed input numbers represent the corresponding values in assumed previous spat collection time (generating time of the scallop), four years traced back before recapture for catch.

22.2.14 Value

The scallop industry increased 32.1 times in value and 23.1 times in production over 30 years from 1970 to 2000 and was valued at more than 80 billion yen in 1998–2000 (Fig. 22.18). This value supports the economic activity of coastal fisheries in north Japan.

If one observes the relations between the amount of production of the scallop in Japan and the price of scallops it can be seen that the price decline began after 1987, when a total production exceeded 300,000 mt, and that tendency continues now. A tendency for

Figure 22.18. Changes in annual value of Japanese scallop, *Patinopecten* (*Mizuhopecten*) *yessoensis* Jay, in Japan, 1970–2000. Source: Ministry of Agriculture, Forestry and Fisheries, Government of Japan, 'Annual report of statistics of fishery and aquaculture production.

price decrease is seen after 1988 when total production exceeded 80,000 mt and continues to do so to this date in Aomori. It is considered that the decreasing price is caused by an increase in the amount of production in Japan on the whole and also imports from China.

The scallop price fluctuated in the ranges of 173–288 yen kg⁻¹ in 1971–1986 and has declined gradually since then. It had a peak of 288 yen kg⁻¹ in 1976. There was much anxiety about production due to the initial occurrence of a mass mortality in the hanging culture in northeast Honshu (east Tohoku) areas of Miyagi, Iwate and Aomori prefectures in the mid-1970's. In Aomori, the price soared suddenly in the next year after mass mortality occurred in 1975 (Fig. 22.19). Additionally, the culture cost rose suddenly at a remarkable rate due to increased oil prices in 1974 making the culture materials from petrochemical products expensive. A secondary peak of 264 yen kg⁻¹ appeared in 1980, because the hanging culture production touched bottom. In 1984 a third peak of 275 yen kg⁻¹ came of the brisk marketability for increasing the export of frozen muscle after the scallop fishery in USA closed. The unit price of yen kg⁻¹ at harvest from hanging culture has been higher than that of catch from sowing culture and wild scallops. In addition, the yearly price on harvest is inversely proportional to the quantity. The market for total harvest is presumed to depend directly on the current marketability and on catch hardly shows a tendency to be directly influenced by the current marketability. The scallop is an export item even now, though export of scallops to France was prohibited in 1990 and domestic consumption had tended to increase. In 1985–1986 the price declined due to

Figure 22.19. Relationship between annual production and price of Japanese scallop, *Patinopecten (Mizuhopecten) yessoensis* Jay, in Japan, 1970–2000. Source: Ministry of Agriculture, Forestry and Fisheries, Government of Japan, 'Annual report of statistics of fishery and aquaculture production.

both the increase in hanging culture production and the good Japanese yen exchange rate. Furthermore, that unit price fell gradually and reached the low level of 129 yen kg⁻¹ in 1996 as the amounts of production of scallop in Japan increased greatly.

22.2.15 Processing

Though scallops produced in Iwate and Miyagi are almost all distributed fresh, most of the scallop is processed for marketing, with 16.3% of fresh scallops in Hokkaido and 2.3% in Aomori consumed in the fiscal year 2001–2002 (Fig. 22.20). Processed scallop products include the frozen, dried, canned, adductor muscle, and boiled meat (soft body). The distribution by scallop processing product in Hokkaido is calculated at four times [A–D] separated as follows: averages for 27 years throughout 1975/76–2001/2002 for the fiscal year (April–March) are presented (1) 22.4% for fresh scallop, (2) 35.5% for frozen muscle, (3) 20.8% for boiled meat, (4) 15.3% for dried muscle and (5) 6.2% for canned muscle and others. [A] Averages for first three years of 1975/76–1977/78 are (1) 57.8%, (2) 4.1%, (3) 17.5%, (4) 16.5% and (5) 4.1%. [B] Averages for second 5 years of 1978/79–1982/83 are (1) 30.7%, (2) 20.9%, (3) 24.4%, (4) 19.9% and (5) 4.1%. [C] Averages for third ten years of 1983/84–1992/93 are (1) 16.8%, (2) 32.6%, (3) 26.6%, (4) 16.3% and (5) 7.7%. [D] Averages for fourth nine years of 1993/94–2001/2002 are (1) 20.1%, (2) 39.3%, (3) 18.8%, (4) 15.7% and (5) 6.0%. Consequently, each time span has a peculiar progress. [A] New processes: where 58% of the production was fresh scallop, and the processed products had a small share. Boiled meat and dried muscle were 17% at the same rate; however, the frozen muscle remained at an especially low rate. Production overwhelmed the processing capacity. In that period, the harvest from hanging culture increased rapidly toward a peak of 1977/78, though the catch was low. The annual harvest and catch were in the ratio of 66.5% to 33.5% and the total reached the first record, more than 100 thousand mt in 1977/78. [B] Developing stage: The fresh scallop decreased to the quantitative bottom in 1982/83; still the yearly average ratio was 30.7%. Frozen and dried muscles and boiled meat increased, especially the boiled meat, which reached a first peak over the harvest amount in 1982/83. The harvest touched bottom due to mass mortality in 1979/80; however, the catch increased rapidly. [C] Growing stage: absolute quantity for processing of every product increased with time. The boiled meat and fresh scallop suddenly increased from 1987 to 1989, the frozen muscle remained high. The frozen muscle and boiled meat increased in the average ratio, and the fresh scallop and the dried muscle decreased. The harvest recovered and exceeded 100,000 mt, sown culture exceeded 200,000 mt too; therefore, the total increased and surpassed 300,000 mt in 1990/91. [D] Mass processing stage: Processing of the frozen and the dried adductor muscle has grown rapidly by having increased the production of wild and sown culture scallop in the Okhotsk Sea. The frozen muscle

Figure 22.20. Changes in annual processing production of Japanese scallop, *Patinopecten (Mizuhopecten) yessoensis* Jay, in Japan, 1975–2000 of fiscal year (April–March). (Source: Hokkaido and Aomori Federation of Fisheries Co-operations survey).

especially came to occupy about 40% of the total production. On the other hand, the production of boiled and fresh scallop decreased gradually because the production of hanging culture scallop remained constant. The wild and sown culture comes to exceed 300,000 mt; therefore, the total increased and surpassed 400,000 mt in 1999/2000. Throughout this period of 27 years, the fresh scallop fluctuated randomly, and the canned muscle and other products decreased.

The distribution by the scallop processing product in Aomori has been calculated by the same method at four times [A-D] separated as follows: averages for 27 years throughout 1975/76–2001/2002 for the fiscal year are presented (1) 2.9% for fresh scallop, (2) 21.5% for frozen muscle, (3) 59.8% for boiled meat, (4) 9.1% for dried muscle and (5) 6.7% for canned muscle and others. [A] Averages for the same products over the first three years of 1975/76–1977/78 are (1) 1.3%, (2) 19.1%, (3) 61.2%, (4) 12.9% and (5) 5.4%. [B] Averages for the next 5 years, 1978/79–1982/83 are (1) 0.6%, (2) 23.6%, (3) 67.5%, (4) 6.2% and (5) 2.2%. [C] Averages for the next nine years, 1983/84–1990/91 are (1) 2.9%, (2) 30.9%, (3) 50.3%, (4) 8.8% and (5) 7.1%. [D] Averages for the next eleven years of 1991/92–2001/2002 are (1) 3.5%, (2) 16.9%, (3) 63.0%, (4) 9.3% and (5) 7.3%. Consequently, each epoch has a peculiar process. [A] New processes: most (60%) of the production was consumed as the boiled scallop, with processed products being a small share. A mass mortality occurred and the production of scallop in Mutsu Bay rapidly decreased. Frozen muscle was 21%; however, the fresh scallop, dried and canned muscle remained at an especially low rate. The annual harvest and catch were in the ratio of 57.2% to 42.7%. [B] Developing stage: Fresh scallop decreased to its ultimate quantitative, 44 mt in 1978/79. Production of frozen muscle and boiled meat increased, especially the boiled meat, which increased rapidly. At that time, the production of roe-on scallop to export to France increased, too. The harvest recovered and exceeded 20,000 mt in 1978/79, surpassing 30,000 mt in 1982/83. [C] Growing processing stage: The boiled meat suddenly increased from 1988 to 1990. Because export to America increased rapidly, the production of frozen muscle remained high and increased in accordance with average ratio, with the other products increasing in the late 1980's as well. The harvest recovered and exceeded 50,000 mt, with sowing culture coming to exceed 200,000 mt; hence the total increased and surpassed 70,000 mt in 1990/91. [D] Mass processing stage: The production of boiled scallop maintained a high level. The production rate of boiled scallop was more than 60% of total production in Mutsu Bay; especially the boiled small one-year-old scallop called 'Hansei-gai' which came to occupy more than 25%. Production of frozen muscle fluctuated at this stage because although export of the frozen muscle to America was favourable from 1997 to 1998, export to France was prohibited in 1990. The production of sowing culture decreased to less than 10,000 mt; therefore, the hanging culture came to occupy about 90% of the total production.

The boiled meat is a significant part of the harvest. The productions of frozen and dried muscles were significantly related to the catch, because scallop body size determines processing methods. Boiled meat is processed from a small scallop harvested within two years of age, while the frozen and dried muscles need to be good quality, large scallops caught at more than three-years-old.

22.2.16 Occurrence of Shellfish Poisoning

Paralytic shellfish poisoning (PSP) and diarrhetic shellfish poisoning (DSP) occurred in Hokkaido in 1978 (Nishihama 1994). Occurrences of PSP and DSP in the scallop industry change the harvest period and the array of processed products. Various countermeasures were taken (Okaichi et al. 1982; Nishihama 1980). A series of food poisonings resulting from mussel and scallop occurred in the Tohoku region in 1976 and the summer of 1977 and the presence of an unknown fat-soluble toxin was revealed (Yasumoto et al. 1978). In Mutsu Bay the regulation for DSP was applied to scallops and mussel in 1988 (Thubata 1982). The toxin levels of PSP in Funka Bay, Pacific Ocean and the Nemuro Strait are extremely high, but in the Japan Sea and northern part of the Okhotsk Sea in Hokkaido are not detected, or are very low (Tables 22.7 and 22.8; Nishihama 1994). Harvest was continued year round until 1977 when the shellfish poisoning limited the harvest. Both poisonings occur from spring to autumn, the catch is limited by PSP, though DSP changes the disposition to processing. The scallop can be distributed when the digestive gland is removed even if DSP has occurred, because DSP is lipid soluble toxin and does not spread to other tissues except for the digestive gland. The digestive glands of scallops are disposed of, and scallops in Mutsu Bay are distributed even if DSP occurs from spring to autumn, because PSP never occurred.

22.3 FUTURE

22.3.1 Technology

There is an unstable element in the natural spat collection in the bay as well as offshore. Spat collection was depressed several times during these ten years in Funka Bay. The cause of the natural spat collection depression should be detected, and a concrete countermeasure must be taken to maintain scallop industries' steady production. It is necessary to develop sustainable seed supplies to maintain production. Seed production in embayment areas such as Saroma Lake and Mutsu Bay may meet the demand and avoid the spat collection depression in the future; therefore, offshore spat collection has to reliably provide more seed for sowing culture.

Recently, there has been a decline in the growth of sowing cultured and hanging cultured scallop, probably caused by overpopulation and environmental conditions (Kurata 1999; Shimada et al. 2000; Kosaka et al. 2002).

New technology and continuous monitoring will be required, such as controlling cultured populations, culturing at low cost, and producing goods of quality, to develop and maintain scallop culture industries in Japan.

22.3.2 Control of Culture

Until now, the study of a carrying capacity level using primary production and feed amount of the scallop in Mutsu Bay, Funka Bay and Saroma Bay, a closed area, were made to prevent overcrowded culture. Similar studies were conducted in the same way even in Tokoro, Saroma and Yubetsu, which are open areas. Limiting mass of the hanging culture will be required with basic consensus of the producers discussed (Aomori Prefecture 1976, 2000; Hokkaido Fish. Res. Tec. Dev. Asso. 1977; 1978; Hokkaido Aquaculture Public Corp. 1983; Offshore Scallop Fishery Synthetic Investigation Special Commissioner 1997a, 1997b). Densities of seeds and surviving scallops have to be controlled in order to increase productivity (Ito et al. 1988b). The cultured and sown level is regulated in accordance with the results of studies in Hokkaido and Aomori. The density of seed sown on culture grounds has been kept at the same level everywhere because erroneous hypotheses that survival rates and cultured standing crops are the same everywhere are still believed. A profitable control for creating a systematic industry based on scientific fact will be developed. The density reduction by removal of scallops has been experimentally managed to avoid over crowded populations caused by high survival rates, concentration, and natural mass recruitment. Furthermore, for sustainable production of a high quality scallop population, introducing a concept of breeding management on scallop culture and genetic management should be carried out (Kosaka 1997b; 1999).

22.3.3 Cost-reduction

The net profit from scallop culture is decreasing because the price is declining rapidly, the materials and equipment have become more expensive and Japanese labour wages have risen. The indispensable sales strategy for the market of not only Japan but also the world is to maintain the price of the scallop. Moreover to keep its profitability, cost-reduction is necessary. In culture, the survival rate has to be improved and the quality must also be improved for a higher price. Furthermore, efficient and cheap materials or equipment must be developed. The labour involved in sowing culture is higher than that of hanging culture because the sowing culture system runs by low handling frequency and highly concentrated operations; therefore, automating sowing culture would be a great advantage in cost-reduction.

22.3.4 Concept

To develop the technology, the concept of scallop mariculture is indispensable. Culture systems need completion by elements of 'Tane-zukuri [making seed]', 'Gyoba-zukuri [making culture ground]' and 'Hito-zukuri [making person]': meaning seed production, culture control, and manpower. Every elemental technical method, know-how and manpower relates and responds to one another.

22.4 PECTEN ALBICANS

The bay scallop, *Pecten (Notovala) albicans* (Schröter, 1802), is called "Itaya-gai" in Japanese, the baking-scallop.

22.4.1 Biology

Bay scallops live on the sandy sea bottom in coastal areas of the temperate zones of China, Taiwan, Korea, and Japan. This scallop is distributed in shallow seas around Japan such as Kyushu, Shikoku, Honshu, and south Hokkaido except the Pacific coasts of east Honshu. In the Japan Sea coasts of Kyushu and Honshu, high density populations have sometimes appeared at depths of 20–120 m off Fukuoka, Yamaguchi, Shimane, and Tottori Prefecture (Hiramatsu 1960; Koga 1963).

The fan shaped valves have symmetrical ear beaks at the umbones. The shell shape is convex in the right valve with a white surface and the left one is flat with a slightly hollowed area below the umbo and brown colouration. The radiating rib number is between 8 and 10 on a right valve. The morphological development of the bay scallop is as follows (Hotta 1977): fertilised demersal eggs of 79 microns diameter reach D-shaped larvae of early veligers of 102 μm in length at two days. Larvae grow into the subsequent developmental stages of umbo 120–160 μm by 10 days, early full-grown 190–210 μm by 14 days and full-grown 154–270 μm with eye spots by 20 days. The pediveliger attaches to the substratum with byssus by 25 days. Attached spat produce the dissoconch of 230–250 μm length by 28 days. The spat grow to 315–356 μm in one month with a daily growth rate of 8.6–16 μm and 1.5–3.6 mm by two months at the rate of 20–140 μm . It becomes a benthic spat which parts from the substratum by three months at 10 mm length at the rate of 2.0–3.0 mm. Juveniles have an adult shell form at 5 cm length and 14 g weight at 6 months. Length and weight are 8 cm and 60 g at one year, 10 cm and 100 g at 1.5 years, 11 cm and 150 g at two years, and 11 cm and 150 g at 2.5 years.

The spawning season lasts from late-January to early-May with spawning occurring actively from mid-February to early-March (Satake et al. 1981). Bay scallops of just one-year-old matures and spawns from April to early June, but tends to spawn later than adult scallop (Moriwaki et al. 1982).

22.4.2 Fishery

The bay scallop fishery has been recorded in the Japan Sea coasts off Tottori Prefecture, San-in district of west Honshu, for more than 180 years (Tanaka 1984). The catch was below 200 mt per year before 1920 as the fishery was conducted by a hand trawl from a rowboat or sailboat and was regulated by scallop size and fishing period. A 1925 catch of 28,000 mt from a large recruitment was harvested after the introduction of powered boats and improvements in catch efficiency. The catch remained below 200 mt in the 40 years since that 1925 peak. A secondary high catch period occurred in 1965–67, and the catch ranged from 13,000–26,000 mt off Shimane and Ishikawa Prefecture. The catch decreased again in the 1980's.

22.4.3 Culture

Natural spat collection was tried in the Shimane Peninsula, Shimane Prefecture from 1978 to 1980 (Oshima 1978) and hanging culture of bay scallops was examined at Oki Island, Shimane Prefecture, in 1977 (Ayama 1986). After this promising result the culture extended to the fishery level. Two and a half million seed were harvested by about 150 fishermen in Shimane Prefecture by 1984. While that harvest slightly increased in the mid 1980's, the culture has become a fluctuating activity of late. After 1985 natural spat collection resulted in low level production (Yoshio et al. 1987; Seimura 1994). This decline caused the seed production levels to fluctuate. Recently the natural stocks have occurred at lower levels. The artificial spat production of bay scallop have been made by the public research organisation in Shimane, Miyazaki, Ishikawa, Hiroshima and private hatchery in Wakayama, but that method is not yet established. The hanging cultures were carried out with the increase in the natural spat collection in Shimane Prefecture at each place until 1985, but declined with the decrease in natural spat collection (Seimura 1991). Enhancement of the bay scallop was planned for 1980–1988 (Tanaka 1984, 1987); however, sowing culture has not developed.

22.5 *CHLAMYS (MIMACHLAMYS) NOBILIS*

The noble scallop, *Chlamys (Mimachlamys) nobilis* (Reeve, 1852), is called “hiougi-gai” in Japanese.

22.5.1 Biology

The noble scallops are distributed on the rocky or sandy sea bottom from the littoral zone to several fathoms depth in southwest Japan. Reproductive cycle of the noble scallop is biannual; the first spawning season from June to July is followed by the second spawning season from October to November. Most male juveniles matured at 8 and 9 months, whereas a few mature females were observed at 11 months of age (Komaru 1988). Fertilised eggs develop into D-shaped larvae by 20–24 hours. The pediveliger of 200 µm length attaches to the substratum with byssus by 2–3 weeks. The scallop grows to 7–8 cm by 1–1.5 years after fertilisation.

The shell colour of noble scallop is controlled genetically. It was argued that blue purple and red purple were dominant to brown, blue purple to red purple and lemon yellow, and blue purple were incomplete dominance to red purple (Nanba 1975).

22.5.2 Culture

The hanging culture is industrialised but the sowing culture is undeveloped (Shiihara 1986). Most fishermen culture scallops as a subsidiary job. So each harvest is kept small to preserve it as a unique local product. The culture is supported by seed from natural spat and artificially raised spat. To stabilise a seed supply, some experiments on artificial seed production have been carried out (Nanba and Nishiyama 1973; Hotta 1973; Shiihara and

Takeda 1978). Artificially produced larvae grow to attached spat at 1 mm shell length by about 40 days in tanks, and then they are caged for intermediate culture in the sea. Shell length becomes 3–5 mm at 2 months and 6–12 mm at three months. From September to November seeds of more than 10 mm are caged for hanging culture and they grow to 10–20 mm at 4 months, 13–31 mm by 5 months and 7–8 cm at 1.5 years. Scallops more than 7 cm are harvested from the next autumn to the following spring.

ACKNOWLEDGMENTS

The authors wish to thank Messrs. Mamoru Kurata and Akira Miyazono for their friendship and constructive discussion. The authors also wish to express sincere thanks to the Hokkaido and Aomori Federation of Fisheries Cooperatives for providing the scallop statistics.

Chapter 23

Scallop Culture in China

Ximing Guo and Yousheng Luo

23.1 INTRODUCTION

Scallops are among the most valuable marine resources in China. Scallops support a major aquaculture industry that is important to economies of China's coastal regions. In the past decade and particularly after the crash of the shrimp culture, scallop farming has expanded rapidly and become the largest mariculture industry in China. Aquaculture production increased by 41 folds between 1986 and 1997 (Fig. 23.1). In 1997, China produced one million metric tons of scallops from aquaculture (MAC 1998), with an estimated value of over US\$1 billion. Compared with scallop aquaculture, scallop landing from wild fishery is negligible. Almost all scallops produced in China (>99%) are now from aquaculture production.

Scallops are found throughout China's 18,000-km coast, on rocky and sandy bottoms and at depths of 5–360 meters. There are over 44 species of scallops naturally occurring in coastal waters of China (Table 23.1). Most of the scallops are found along the southern coast (below 25°N) and in South China Sea (Wang 1983; Qi et al. 1989; Xu 1997). Only a few species are of commercial importance. The zhikong scallop (*Chlamys farreri* Jones et Preston) in the north is by far the most important commercial species. It is the dominant aquaculture species and accounts for over 60% of the total scallop production in China. The huagui scallop (*Chlamys nobilis* Reeve) in the south is also cultured commercially, but the production is limited to only about 2% of the total production.

Several non-native species have been introduced for aquaculture production, including the bay scallop (*Argopecten irradians* Lamarck) from North America, the Japanese scallop (*Patinopecten yessoensis* Jay) from Japan, and the great scallop (*Pecten maximus* Linnaeus) from Europe. The bay and Japanese scallops are cultured commercially in China. Aquaculture production of bay scallops increased considerably in recent years due to severe summer mortalities of zhikong scallops since 1997. The great scallop is being tested for aquaculture in the Dalian area.

This chapter focuses on the biology of the native zhikong scallop, and the current status and practices of the scallop aquaculture industry in China.

Figure 23.1. Aquaculture production of scallops (fresh whole weight) in China from 1980 to 1998. The sharp decrease in 1998 is caused by massive summer mortalities of the native zhikong scallop.

Table 23.1

A list of scallop species naturally occurring in coastal waters of China.

Species	Distribution
<i>Amussium japonicum formosum</i> Habe	18°N – 25°N
<i>Amussium japonicum balloti</i> Bernardi	8°N – 25°N
<i>Amussium pleuronectes pleuronectes</i> Linnaeus	8°N – 20°N
<i>Amussium pleuronectes nanshaensis</i> Wang	5°N – 12°N
<i>Annachlamys reevei</i> Adams et Reeve	22°N – 25°N
<i>Annachlamys macassarensis</i> Chenu	22°N – 25°N
<i>Anquipecten superbus</i> Sowerby	22°N – 25°N
<i>Anquipecten lamberi</i> Souverbie	22°N – 25°N
<i>Bathyamussium jeffreysi</i> Smith	10°N – 30°N
<i>Bractaechlamys elegans</i> sp. nov.	18°N – 19°N
<i>Bractaechlamys quadrilirata</i> Lischke	19°N
<i>Bractaechlamys schmeltzii</i> Kobelt	8°N – 18°N
<i>Bractaechlamys teramachii</i> Webb	20°N – 25°N

<i>Chlamys albolineata</i> Sowerby	18°N – 22°N
<i>Chlamys asperulata</i> Adams and Reeve	18°N – 22°N
<i>Chlamys farreri</i> Jones et Preston	25°N – 40°N
<i>Chlamys gloriosa</i> Reeve	18°N – 22°N
<i>Chlamys irregularis</i> Sowerby	20°N – 25°N
<i>Chlamys jousseaumei</i> Bavay	15°N – 22°N
<i>Chlamys larvatus</i> Reeve	18°N – 22°N
<i>Chlamys lemniscata</i> Reeve	18°N – 28°N
<i>Chlamys lentiginosa</i> Reeve	20°N – 25°N
<i>Chlamys madreporarum</i> Sowerby	18°N – 22°N
<i>Chlamys miniacea</i> Lamarck	20°N – 25°N
<i>Chlamys nobilis</i> Reeve	19°N – 22°N
<i>Chlamys squamata</i> Gmelin	18°N – 25°N
<i>Chlamys valdecostata</i> Melvill	20°N – 22°N
<i>Comptopallium radula</i> Linnaeus	22°N – 25°N
<i>Ctenamussium sinensis</i> Wang	25°N – 32°N
<i>Cryptopecten bullatus</i> Cautzenberg et Bavay	10°N – 22°N
<i>Cryptopecten complanus</i> Wang	25°N – 30°N
<i>Cryptopecten inaequalis</i> Sowerby	20°N – 25°N
<i>Cryptopecten nux</i> Reeve	15°N – 22°N
<i>Cryptopecten oweni</i> De Gregorio	20°N – 25°N
<i>Cryptopecten vesiculosus</i> Dunker	22°N – 32°N
<i>Decatopecten plicus</i> Linnaeus	22°N – 25°N
<i>Decatopecten striatus</i> Schumacher	22°N – 25°N
<i>Decatopecten amiculum</i> Philippi	22°N – 25°N
<i>Delectopecten macrocheiricola</i> Habe	25°N – 32°N
<i>Gloriopallium pallium</i> Linnaeus	22°N – 25°N
<i>Pecten albicans</i> Schroter	22°N – 33°N
<i>Pecten excavatus</i> Anton	25°N – 32°N
<i>Pecten pyxidatus</i> Born	5°N – 28°N
<i>Polynemamussium intuscostatum</i> Yokoyama	5°N – 22°N
<i>Propeamussium sibogai</i> Dautzenberg et Bavay	5°N – 22°N
<i>Propeamussium stella</i> Wang	5°N – 22°N
<i>Propeamussium gracilis</i> Wang	5°N – 22°N
<i>Propeamussium caducum</i> Smith	5°N – 22°N
<i>Propeamussium watsoni</i> Smith	22°N – 32°N
<i>Semipallium fulvicostum</i> Adams et Reeve	19°N – 21°N
<i>Semipallium spectabilis</i> Reeve	19°N – 25°N
<i>Semipallium tigris</i> Lamarck	18°N – 19°N
<i>Semipallium xishaensis</i> sp. nov.	15°N – 20°N
<i>Serratovola tricarinata</i> Anton	8°N – 25°N
<i>Volachlamys singaporinus</i> Sowerby	18°N – 28°N
<i>Volachlamys hirasei</i> Bavay	30°N – 41°N

23.2 ZHIKONG SCALLOP

23.2.1 Shell Morphology

Shell morphology and anatomy of the zhikong scallop have been described in details elsewhere (DFC 1979; Wang 1983; Qi et al. 1989; Wang et al. 1993). The two valves of zhikong scallop are nearly equal. The external colour ranges from orange, light brown to purplish brown. The left valve is more convex than the right valve. The anterior auricle is larger than the posterior auricle on both valves. The anterior and posterior auricles of the left valve, and the posterior auricle of the right valve are triangular. The anterior auricle of the right valve is rectangular and forms the byssal opening. Six to ten denticles occur on the ventral side of the byssal opening. There are 10 major radian ribs (ranging from 8 to 13) on the left valve, with minor ribs between them. There are 20 to 30 less convex ribs on the right valve. Sharply pronounced scales occur on the ventral side of both valves. The interior surface of both valves is usually smooth and glossy white or pink in colour.

23.2.2 Distribution

Zhikong scallops are found from the coasts of Liaoning province, latitude 40°N, to the shores of Fujian province, latitude 25°N. Outside China, zhikong scallops are found in waters of Korea and Japan. Distribution is patchy throughout the range and no extensively abundant beds occur. Major populations occur on southern Liaoning peninsula, and the north and south coasts of Shandong peninsula, at depths of 5–60 m. At these waters the current is unblocked, the nutrients rich and the bottom solid. Zhikong scallop has well-developed byssus and uses it to attach onto rocks and other hard surfaces. Zhikong scallop can sever byssus and relocate under adverse conditions. Young scallops are particularly mobile.

During 1980 and 1984, the National Fishery Resource Survey showed that population density of zhikong scallop in Jin county on eastern Liaoning peninsula was 4.4 scallops (or 228 g) per square meter. In Changhai county, the average density was 2.3 scallops (or 126 g) per square meter. Total scallop resources in the above areas were estimated as between 200 and 750 t. In Lushun area at the western end of Liaoning peninsula, the average density was 1.8 scallops (or 98 g) per square meter. Total biomass of Lushun area was about 230 t. In Rongcheng county at the eastern end of Shandong peninsula, population density was about 0.8 scallops (or 43.7 g) per square meter. In Changdao county of the northern Shandong peninsula, population density was estimated as between 0.25 and 1.0 scallops (or 17–50 g) per square meter. Total resource in the above two areas was about 400 tons. In other areas such as Qingdao and Weihai waters of Shandong peninsula, zhikong scallops also occur, but no statistics is available.

Adult zhikong scallops are generally between 55 and 85 mm in shell height. The maximum shell height is about 100 mm. Figure 23.2 shows the size frequency distribution of scallops collected from Shandong waters by Zhang et al. (1956). In general, the distribution is skewed towards larger animals. The majority of scallops are

Figure 23.2. Size frequency distribution of zhikong scallops collected from Shandong waters in three years (Zhang et al. 1956).

between 60 and 80 mm. Scallops smaller than 50 mm or larger than 85 mm are rare and account only about 2% of the population. Similar distributions are found in scallops from other areas. Scallops from Jin county of Liaoning province have an average shell height of 72 mm and an average weight of 62 g. In Lushun area, scallops are between 33 and 87 mm in shell height, with an average of 74 mm, and 54.4 g in whole body weight.

23.2.3 Growth

Zhikong scallop grows fast during the first two years. Growth slows down considerably after two years of age. Zhang et al. (1956) studied the growth of scallops maintained in baskets in Qingdao area over a five-year period. Their results show that scallops reach a shell height of 23 mm in the first year (0.5 years in age), 50 mm in the second year, 64 mm in third year, 70 mm in the fourth year, and 76 mm in the fifth year (Fig. 23.3). The percent shell growth attained in Year 1 to 5 is 30% (first half year), 35%, 19%, 8% and 8%, respectively.

Growth rate of Zhikong scallops is strongly influenced by water temperature. Although zhikong scallop tolerates a wide range of water temperatures (-1.5 – 30°C), extreme temperatures greatly reduce growth. Growth is nearly absent during winter months when water temperature is below 5°C . Growth rate increases rapidly with

Figure 23.3. Growth in shell height of experimental zhikong scallops maintained in baskets in Qingdao waters (Zhang et al. 1956).

increasing temperature in the spring, and the fastest growth is found at 16–18°C (Yang et al. 1999). Growth slows down sharply with increasing temperatures beyond 23°C. Zhikong scallops in Dalian area have two growing periods. The first period is between May and July when the water temperature is at 14–21°C (Fig. 23.4). The second period of growth is between September and October when water temperature is between 22 and 14°C. Under optimal conditions, zhikong scallops can grow up to 9 mm per month. In northern Shandong peninsula, the main growing season is from early May to early July, and the second growing period is relatively insignificant (Fig. 23.5).

Growth of cultured scallops depends on culture density. In 1979, the Fisheries Institute of Jin County tested effects of density on growth at the same cultural depth. The results are summarised in Table 23.2. Growth of scallops decreased with increased density throughout the testing period. Depth may also affect the growth of cultured zhikong scallop. Generally, scallops suspended near the surface grow faster than those at deep waters, when there is little fouling. However, seaweeds and other fouling organisms, which grow well near the water surface, may seriously block water flow to lantern net close to the surface and limit food supply. Near the sea floor, the current is weak and the presence of mud and sand is unfavourable for the growth of scallops. Lantern nets are often deployed close to the surface (1–3 m) and lowered to deeper waters (3–5 m) in seasons when fouling organisms reproduce. They are always above the sea floor.

Figure 23.4. Relationship between water temperature and monthly increase in shell height of zhikong scallop during a cultural cycle in Dalian area.

23.2.4 Reproduction

Apart from occasional hermaphroditism, sexes in zhikong scallop are separate with an approximately 1:1 sex ratio. Zhang et al. (1956) examined the sex ratio of 6,025 scallops from a natural population, and found 52.4% females and 47.6% males. The colour of female gonad is reddish orange and the male is milky white. Zhikong scallops can reach sexual maturation in their first year, but the size at maturation depends on growth rate.

Gonad development and reproductive cycle of zhikong scallop depends on water temperature and food supply. From histological examinations, five main stages of gonadal development have been recognised in scallops from Qingdao area: 1) proliferation stage, from January to March; 2) growing stage, from April to May; 3) mature stage, from May to September; 4) spawning stage, from May to October; and 5) spent stage in November and December (Liao 1983).

Zhikong scallops usually have two spawning seasons in a year: one in mid-May to June and the other in late September to October. The gonad index (gonad weight/body weight $\times 100$) of zhikong scallops in Dalian area increases sharply in late April (at 8–9°C) and reaches its first peak in mid June (around 16–19°C) (Fig. 23.6). After spawning, the gonad index drops to its lowest value in late July - August (22–24°C). The gonad index rises to its second peak in mid-September, and declines again in early October. Spawning time varies annually due to variations in water temperature. For example, the period of first spawning around Haiyang Island of Liaoning province occurred in late June/early

Figure 23.5. Annual variation of instantaneous growth rate (IGR) in dry-tissue weight of zhikong scallop in Jinggouwan and Yueliangwan areas of northern Shandong peninsula (Yang et al. 1999).

July in 1983, through out in July in 1984, and from early July to early August in 1985. Spawning time may differ by up to 30 days from year to year.

Mature eggs of zhikong scallop are about 65–72 μm in diameter. Sperm remain active for 12 hours after being released (at 19°C). At 18–20°C, fertilised eggs release polar body I at 15–20 min, polar body II at 25 min, and reach D-stage at 24–28 hours post-fertilisation. The average size of D-stage larvae is about 110 μm in length x 87 μm in height. Development to metamorphosis and settlement takes about 15 days at 20–23°C.

Table 23.2

Mean shell height (mm) of zhikong scallops cultured at different densities.

Duration (days)	Cultural density (scallop/basket)				
	50	100	200	400	600
25	6.6	6.5	5.5	5.0	4.7
43	7.4	7.0	6.7	6.9	4.7
76	8.5	6.6	6.7	6.4	6.1

Figure 23.6. Seasonal changes in gonad index of zhikong scallop in Dalian waters, showing two spawning seasons (Month 4 = April; 5 = May; 6 = June, etc.).

Traditionally, recruitment rate of zhikong scallops is low in most areas of Bohai and Yellow Seas. Strong one-year classes (<30 mm) have been observed in Chrysanthemum Island waters, off Liaoning coast. Because of large-scale aquaculture since late 1980's, recruitment from cultured populations has become extremely abundant in several areas (Guo et al. 1999). The cultured populations are derived from hatchery-produced seed in early 1980's. There are concerns that the cultured populations are inbred because of the founding population effect. The loss of the genetic diversity is considered as one of the potential causes for the heavy mortality experienced by zhikong scallops since 1996.

Natural predators of zhikong scallop include fish, echinoderms, crabs and snails, which primarily feed on young scallops less than 10 mm. Pests and fouling organisms include the pea crab, *Pinnotheres sinensis* Shen, boring worms such as *Polydora*, sponges, barnacles, oysters and mussels.

23.3 OTHER SCALLOP SPECIES

23.3.1 Huagui Scallop

Huagui scallop is a warm water species. It has a larger adult-size and faster growth than zhikong scallop. It is the main commercial species in southern China.

Shells of the Huagui scallop are nearly circular, with the upper (left) valve more convex than the lower (right) one. The external colour of left valve appears pinkish

brown, yellowish brown or light red with cloudy grains. Both valves have 23 ribs. The distance between rows of ribs is smaller than the width of the ribs. The anterior and posterior auricles of the left valve are triangular, with the anterior auricle being slightly larger and having 7–8 coarse ribs on the surface. The anterior auricle of the right valve is smaller than the posterior article and has four coarse ribs. The posterior auricle is triangular with the byssal opening on its ventral side and numerous fine ribs. The internal surface of both shells is generally yellowish brown and has as many ribs or grooves as the external surface.

Huagui scallops are primarily distributed in the South China Sea, and from eastern Japan as far south as Indonesia. Its distribution in China is mostly limited to coasts of Zhaoyan, Haimen, Jilang, Aotau, Guanghai, Jiapo of Guangdong province and Xincun of Hainan province. Abundant areas of huagui scallop are found along the coast of Daya Bay in Guangdong. Huagui scallops are usually distributed from the lower intertidal zone to subtidal depths of more than 360 m. They occur on subtidal rocky or sandy bottoms with good current and clear water. Usually they are attached by byssus to rocks or other substratum. Sometimes, they also lay freely on the right valve. Huagui scallops have a patchy distribution and are not particularly abundant in any one locality. Population density is generally not more than one scallop per square meter, and the biomass may occasionally reach 38 g per square meter.

Temperature range in natural habitats of huagui scallop is between 8 and 32°C. The optimum temperature of growth is between 20 and 25°C. In Guangdong province, huagui scallops exhibit rapid growth from May to September. Hatchery produced seed may grow to a shell height of 68 mm in one year in waters of Guangdong province. The largest individual grown in suspended culture may reach 120 mm in three years.

Sexes of huagui scallop are separate. Mature eggs are about 65 μm in diameter. Huagui scallops have high fecundities, although it depends on the size of the individual. Females usually produce about 3–7 million eggs, and the largest individuals may produce up to 15 million eggs. Huagui scallops have two spawning seasons on the northern coast of South China Sea. In Sunwei port of Guangdong province, the first peak of spawning occurs between late April and the first ten days of May when water temperature reaches 25 to 28°C. The second peak is between August and September when water temperature drops from 29 to 21°C. In Daya Bay, the first peak occurs between April and June, and the second peak between October and December (Cui 1980).

Larval development of huagui scallop has been studied in the laboratory (Zhang 1982). At 26–29.5°C and salinities of 27–29 ‰, development from fertilised egg to D-stage takes about 22 hours (shell length 101 μm x shell height 82 μm). Larvae usually settle at 230 μm in about 14 days at 26°C. At temperatures of above 28°C, larval development is shortened to 9 days (Zhang 1982).

23.3.2 Non-native Species

At least three species have been introduced to China for aquaculture production. The first species introduced is the Japanese scallop. It was introduced from Japan to Qingdao and Dalian areas in the late 1970's. The Japanese scallop is a cold-water species and

cultured only in northern provinces, Liaoning and the north side of Shandong peninsula. Japanese scallops do poorly in regular lantern nets. They grow well when cultured using the ear-hanging method. They have difficulties with high summer temperatures in Bohai Sea, which often reach 25–28°C. The yield of Japanese scallop is probably less than 1% of the total scallop production in China. Although its yield is low, Japanese scallop is larger in size and enjoys a higher market price than zhikong and bay scallops.

The bay scallop was introduced from the United States to Qingdao in 1982 (Zhang et al. 1986). Of the original shipment, twenty-six bay scallops survived and spawned in January 1983, producing the first generation of bay scallops in China. Juvenile scallops reached an average 6.9 mm in May and were transferred to culture sites in Shandong and Fujian provinces. Scallops grew to 50 mm by September and 59 mm by December 1993. Market size, 50–60 mm, can therefore be reached within a year. This is a major advantage over the zhikong scallops, which usually take 1.5–2.0 years to reach market size. The shorter turn-around time of bay scallops is partly due to its faster growth, and partly to the fact that they are spawned in the early spring (or late winter) so that they catch a full growing season. Because zhikong scallop seeds are collected in the fall, they miss most of the first growing season. Because of the short grow-out time, bay scallops quickly gained acceptance by scallop farmers, and aquaculture expanded rapidly after 1984. By early 1990, the annual production of bay scallops had reached to about 200,000 tons. Bay scallop culture production has declined somewhat in early 1990's. It accounted for about 15–18% of the total scallop production. Because of the recent mortality problem in zhikong scallops, bay scallop culture is on the increase again.

The great scallop was introduced from France to Dalian in 1999. About three million F1 seed have been reared to 20–30 mm. They are being evaluated in Dalian area.

23.4 FISHERY

Scallops have been harvested in China for centuries, but the yield has always been limited. Scallop fishery reached its highest level in the 1950's, with an annual yield of about 3,000 tons of whole scallops. Scallop resource and landing declined in the 1950's because of over-fishing.

Zhikong scallop is the main species targeted by the fishery. Scallops were harvested by divers and trawl nets in depth less than 30 meters. Before the 1960's, scallops were mainly harvested by divers equipped with man-powered wooden boats, air compressors and diving suits. Air-compression and navigation were all done by hand. Dives were generally carried out near shores or around isles in depths less than 20 m. In the early 1970's, diesel-powered vessels were introduced, and fishing grounds were extended. Nevertheless, the fishing depth was never beyond 30 m. By the 1980's, small dredges were employed in some areas, and the fishing depth increased to more than 30 m.

Fishing grounds for zhikong scallops are mainly in Bohai Sea and the northern end of Yellow Sea. The number of divers back in the 1950's was about 150 and by the 1960's, the number of scallop fishing boats was declining. There were about 100 boats in operation in 1990. Scallops are not the only species harvested by divers. Other species harvested include abalone, sea cucumber and snails. In the 1950's, the annual yield of

zhikong scallop was between 1,000–1,500 t (fresh) in Shandong province and about 2,000 t in Liaoning province. By the 1960's, the yield was absent in Shandong and in Liaoning had declined to a few hundred tons. Now, due to the development of raft culture, scallop resources in Liaoning and Shandong waters have recovered. Current landing from scallop fishery is not reported in official statistics and negligible compared to aquaculture production.

For zhikong scallops, a seasonal restriction, from May 15–July 31, has been introduced in the northern parts of Yellow Sea, and a size limit of 70 mm in shell height is also in place. No area closures have been enacted.

Huagui scallops are also harvested by divers and trawl nets. Fishing grounds are usually within 1–5 km from the shore. Fishery landing of huagui scallop has been limited since ancient times. Annual production has never reached over 100 t fresh weight. Most huagui scallops are marketed live.

23.5 AQUACULTURE

23.5.1 Species and History

China has a long history of culturing marine molluscs. Traditional molluscan culture dates back to over 2,000 years ago, but it is primarily limited to the “traditional four” species: oysters, blood cockle, razor clam and *Ruditapes* clams (Guo et al. 1999). Modern molluscan aquaculture developed after 1949 and went through a period of rapid expansion since the early 1980's. In 1998, China produced 7 million metric tons of marine molluscs from aquaculture, which accounts for 81% of mariculture production (MAC 1999).

Compared with the culture of other molluscs, scallop aquaculture is relatively new. Over-fishing and the decline in wild fishery in the 1950's led to studies on scallop biology and aquaculture. Studies in the 1950's and 1960's focused on taxonomy, distribution and reproductive characteristics of native scallops. Experimental culture of scallops began in 1968. Key technologies for hatchery production, seed collection and grow-out were developed between 1973 and 1977 (DFC 1979; Wang et al. 1993). Scallop aquaculture became a mature industry in the early 1980's and expanded rapidly between 1986 and 1997 (Fig. 23.1). In 1979, China produced only 35 tons of scallops. In 1985, scallop production exceeded 10,000 t for the first time. In 1997, over 1 million tonnes of scallops were produced from aquaculture, and fishery production became negligible in comparison (MAC 1998). In 1998, however, massive summer mortality of zhikong scallop caused a 37% decline in aquaculture production (MAC 1999).

Scallops are mainly cultured in Bohai and Yellow Seas in the north. Shandong province alone produced 84% of the national total in 1996 (Guo et al. 1999). Liaoning province, with 14% of the national production, was the second largest producer. Four southern provinces, Fujian, Zhejiang, Guangdong and Hainan, produced about 2% of the national total.

Currently there are four major species cultured in China: the zhikong scallop, bay scallop, huagui scallop and Japanese scallop (Fig. 23.7A and B). The native zhikong scallop is the most important species for aquaculture, accounting for over 80% of the total

scallop production. The introduced bay scallops account for about 15–18% of the total production. Huagui and Japanese scallops together may account 1–3% of the total. Zhikong scallop is primarily cultured in north China, particularly in Shandong and Liaoning provinces. Rizhao, in southern Shandong, probably represents the southernmost site for zhikong scallop culture.

23.5.2 Collection of Natural Seed for Zhikong Scallop

Zhikong scallop culture was first developed using hatchery-produced seed, which were first developed in 1974. For many years after 1974, zhikong scallop culture used exclusively hatchery-produced seed. As scallop aquaculture grew, cultured populations became so large that they provided abundant recruitment for seed collection. In 1984, annual collection in Shandong waters reached 2.5 billion seed. In 1986, collection from Liaoning waters also reached 0.5 billion seed. In 1996, one of the most productive bays in north Shandong produced about 130 billion scallop seed, all from cultured populations. High levels of reproduction of cultured populations provided sufficient natural seed for aquaculture use in recent years. There has been virtually no hatchery production of seed for zhikong scallops.

Protocols for seed collection have been well established through years of research and experience (DFC 1979; Wang et al. 1993). Successful collection involves site selection, preparation of collection material, and forecasting collection dates by observing gonadal development, and larval stages and density at the collection site. Seed are usually collected using spat bags (30 x 40 cm, 1.2–1.5 mm mesh) stuffed with nylon screens (about 100 g). Collectors are hung on the floating raft below the surface. A string of collectors contains about 10–12 bags. A typical raft is about 60 m long and carries an average of 500–600 strings. Each bag may collect 100 to 1,000 spat depending on the location, season and year. The depth for deploying collectors varies among species and location. For zhikong scallops, seeds can be collected at depths of 2 and 9 m, usually best at 6–8 m (Wang et al. 1993).

Zhikong scallop culture primarily uses summer seed from the first spawning season, which set between late June and mid-July (Table 23.3). Spat in the collectors are left undisturbed until harvest in early October at a commercial size of about 5–10 mm. Commercial seed are over-wintered at nursery sites on the sea until the following March when they reach about 30 mm and are ready for grow-out. The period of culturing 10-mm seed to 30-mm juveniles is referred to as seed nursery. It is conducted at selected areas on the sea using lantern nets with a small mesh (4–8 mm).

23.5.3 Hatchery Production of Bay Scallop

Because the bay scallop is a non-native species, seed are exclusively hatchery-produced. Hatchery production of bay scallops is similar to that for other marine bivalves. Conditioning of brood stock begins in February (Table 23.3), by raising water temperature

Table 23.3

Milestones of typical culture cycles for zhikong and bay scallops.

Month	Zhikong Scallop	Bay Scallop
Feb.		Broodstock conditioning
March		Spawning, hatchery rearing
April		Spawning, hatchery rearing
May	Forecast larval settlement	Hatchery rearing to 1 mm, spat nursery
June	Deploy spat collectors	Spat nursery to 5 mm, seed nursery
July	Deploy collectors	Seed nursery
Aug.	Monitoring spat growth in collectors	Seed nursery to 20 mm
Sep.	Monitoring spat growth in collectors	Grow-out
Oct.	Harvest 10 mm seed, seed nursery	Grow-out
Nov.	Over-winter seed nursery	Harvest at 60 mm
Dec.	Over-winter seed nursery	Harvest at 60 mm
Jan.	Over-winter seed nursery	
Feb.	Over-winter seed nursery	
March	Grow-out with 30 mm juveniles	
April	Grow-out	
May	Grow-out	
June	Grow-out	
July	Grow-out	
Aug.	Grow-out	
Sep.	Grow-out	
Oct.	Grow-out	
Nov.	Harvest at 60–70 mm	
Dec.	Harvest at 60–70 mm	

and intensive feeding. Hatchery production usually occurs between March and May. Bay scallops are hermaphroditic. They are air-dried and then immersed in warm seawater to induce spawning. Thousands of mature scallops, placed in dozens of lantern nets, are induced to spawn in large concrete tanks, ranging from 10 to 100 cubic meters. When the desired egg density is reached (about 50 mL⁻¹), brood scallops are moved to the next tank to continue spawning. The optimal temperature for larval rearing is about 22–23°C. The first water change is made as soon as the larvae reach D-stage, usually in 24 hours. The optimal culture density is between 4 and 10 larvae mL⁻¹.

Figure 23.7. Scallop culture in China. A, the introduced bay scallop (upper) and the native zhikong scallop (lower) cultured in Shandong. B, the Japanese scallop cultured in Dalian. C, ropes made from palm tree fibres used for the collection of scallop spat and seaweed seedlings in hatcheries. D, suspended longlines used for the culture of scallops, as well as abalone, Pacific oyster and seaweeds in Rongcheng, Shandong province. E, lantern nets used for scallop culture. F, zhikong scallops are harvested at 1.5 years of age. Photos are reprinted from Guo et al. (1999).

Scallop larvae are fed with unicellular algae. Commonly used algae species include *Platymonas subcordiformis*, *Isochrysis galbana*, *Dunalliella* sp., *Phaeodactylum tricornutum*, *Nitzschia closterium*, *Chaetoceros muelleri*, *Dicrateria zhangjianensis* Hu. var. sp., *Isochrysis galbana*, *Heterogloea* sp., and *Chlorella* sp. The species of algae are selected according to the age/size of the scallop larvae. Earlier stages are fed with small species, later stage are usually fed with large species. At the present, most hatcheries use a mixture of several species for feeding. Vitamins and antibiotics are commonly used during larval culture.

At 22–23°C, bay scallop larvae usually reach the eyed-stage (170–190 µm) in 10 to 11 days at which time spat collectors are placed in the tanks. Two common types of spat collectors are used. One is a rope-curtain made from natural palm tree fibre (Fig. 23.7C). The other is polyethylene or nylon nets/screens. Spat, which attach to the collectors by byssal threads, are cultured in the hatchery until they reach 500–600 µm, after which they are moved out of the hatchery for spat nursery. The best spat nurseries are large shrimp ponds. Commercial seed are sold at a size of 5–10 mm. They go through a seed nursery period before reaching 20 mm and being deployed for grow-out. Scallops are harvested between November and December (Table 23.3).

Most of the bay scallop industry was developed using the 26 scallops first introduced in 1982, and there had been signs of inbreeding such as larval and juvenile mortality. Several new introductions have been made to expand the gene pool. Both the northern (*Argopecten irradians irradians*) and southern (*Argopecten irradians concentricus*) subspecies of bay scallops have been introduced to China. The population introduced from eastern Canada, is valued in China for its higher meat ratio. The Canadian population is an F3 generation of scallops introduced from Massachusetts (Scarratt 2000).

23.5.4 Grow-out

Although several other culture methods (such as ear-hanging and tube-cages) have been used in the past, lantern nets on suspended longlines are now the dominant form of grow-out for all scallops cultured in China (Fig. 23.7D). Lantern nets are multi-layered cylinders, with 8–10 layers of discs (35 cm in diameter), connected and coated with a mesh screen (Fig. 23.7E). For zhikong scallops, commercial seed, about 10 mm in size, are deployed in lantern nets in October for seed nursery and over-wintering (Table 23.3). About 200–300 seed scallops are stocked in one layer, or 2000–3000 per cage. Next spring, scallops are thinned to grow-out densities of 50–80 per layer or 400–500 per cage for grow-out. The recommended grow-out density is 30–35 per layer for zhikong scallops, 25–30 per layer for bay scallops, and 15–20 per layer for Japanese scallops (Wang et al. 1993). In reality, higher densities are often used by farmers. The lantern nets are hung on longlines, which are usually 80–100 m long and supported by rubber floats. Fouling of scallop cages is a common problem. Fouling organisms and mud must be cleaned regularly. Zhikong scallops usually reach market size, 60–70 mm, by December or 1.5 years old (Fig. 23.7F). Bay scallops are harvested in December of the same year (or 8 months old) at 60 mm.

Lantern nets are not well suited for culturing Japanese scallops. Because adult Japanese scallops have no byssus and behave differently, they are easily injured or killed from cutting into each other. Single-compartment cages have been developed in Weihai area and greatly improved the survival and growth of Japanese scallops.

Polyculture systems of scallops and other species are developed to fully utilise the primary productivity and maximise income. Polyculture of scallops and kelp are commonly practised. In Liaoning waters, for example, 50 vertical strings of scallops and 34 horizontal strings of kelps are simultaneously hung between two longlines 5–6 m apart. Bay scallops are also cultured on the bottom of shrimp ponds. Scallops and sea cucumbers are sometimes cultured in the same lantern nets. Sea cucumbers feed on seaweed and other fouling organisms on the cage. They are also highly priced seafood in China.

Zhikong scallops have been suffering from massive summer mortalities since 1996. Mortality in 1998 caused a 37% decline in production, with an estimate loss of about US\$360 million. Mortality generally begins in late July or early August as the water temperature reaches and exceeds 28°C. It lasts for about 20 days and ends when the temperature begins to decrease. The summer mortality was first observed in 1994. It has worsened in recent years. Both 1994 and 1995 were warmer (by 2°C and 1°C, respectively) than normal. Temperatures in 1996 were more typical and the death rate lessened. Mortality worsened in 1997–98, reaching 60–80% or more in many areas throughout Shandong and Liaoning provinces. On June 3, 2000, we deployed zhikong scallops at three sites along Shandong coast: Jiaonan on the south side, Penglai and Yantai on the north side of Shandong peninsula. All three sites experienced heavy mortalities in late July and August. Mortality at Jiaonan occurred earlier than the other two sites because of its southern locality and higher water temperatures. By August 29, 2000, cumulative mortality reached 92% at Jiaonan, 86% at Yantai and 88% at Penglai (Xiao 2002). Bay scallops are generally not affected.

There are several suspected causes for the summer mortality, although they have not been studied extensively. Most scientists and farmers in China believe that the mortalities are caused by a combination of over-crowding, high summer temperature and deteriorating water quality. Scallop farmers often culture scallop at 2–3 times the density (30–35/layer) recommended by local scientists. The number of longlines and culture plots (not just for scallop culture) has been increasing rapidly in recent years, and may have exceeded the carrying capacity of many coastal areas. Over-crowding at both cage and bay level may have added considerable stress to the culture environment. A haplosporidan parasite of the type responsible for extensive mortalities in oysters in the United States was identified in bay scallops in China, but there was no evidence that it was causing mortalities in that species or that it had been transferred to zhikong scallops (Chu et al. 1996). Finally, there is also the suspicion that the scallop stock is genetically inbred. Because all seed are collected from cultured populations, which were originated from hatchery production during the late 1970's and early 1980's, it is possible that some inbreeding occurred. Hybrids between the Chinese and Korean or Japanese varieties of zhikong scallop tend to survive better than local seed.

23.6 HARVEST, PROCESSING AND MARKETING

Harvest season generally occurs between autumn and winter. Commercial size varies between species: 60 mm in height for zhikong and bay scallops; 65 mm for huagui scallop, and 70 mm for Japanese scallop. Some scallops are sold live to local seafood markets. The price of live scallops varies greatly depending on the season and year. Most of the cultured scallops are processed.

Traditionally, most of scallops are processed into “dry shellfish”, a traditional name for dried scallop adductor muscles. “Dry shellfish” is processed in three ways:

1. Fresh process: After harvest and cleaning in seawater, adductor muscles are placed in seawater containing 2% fine salt for 10 minutes, then scooped up from the water and dried in the sun.
2. Cooked process: Fresh adductor muscles are placed in 80°C seawater with 2% fine salt for 5 minutes, immediately cooled in flowing water, and then air-dried.
3. Steamed process: Whole scallops are steamed lightly for the valves to open, the adductor muscles removed, cleaned with seawater and dried in the sun. It is important that scallops are not over-cooked.

“Dry shellfish” are marketed in China and other parts of Asia. In China, the price of “dry shellfish” is about 60–165 RMB (US\$7–20) per kg depending on the size and quality.

Since the late 1980's, scallops are processed into frozen products for export to North America and other regions. During the 1990's, many modern seafood-processing plants have been built with mechanised lines and according to international standards. Currently most of the scallops harvested are processed into Individually-Quick-Frozen or IQF adductor muscles. During the early 1990's, a large fraction (>60%) of the scallop production is exported. The domestic market has been growing rapidly. Because of the strong domestic demand and the summer mortality problem, only a small fraction of scallops is currently exported. China also imports sea scallops from North America.

ACKNOWLEDGMENTS

The authors sincerely thank all colleagues and friends for their valuable input and comments, particularly Professors Fengshan Xu, Hongsheng Yang, Ms. Jie Xiao and Dr. Yongping Wang of the Institute of Oceanology, Chinese Academy of Sciences; Professors Ziniu Yu and Zhaoping Wang of Qingdao Ocean University; Professors Rofei Wei, Zhenlong Xu and others of Liaoning Marine Fisheries Research Institute; and Dr. Huiping Yang of HSRL, Rutgers University. This work is partly supported by a grant from National Natural Science Foundation of China (No. 39825121), NOAA's US-China Joint Program in Marine Living Resources and Rutgers University (contribution No. IMCS-2003-24).

Chapter 24

Scallops Fisheries and Aquaculture of Northwestern Pacific, Russian Federation

Victor V. Ivin, Vasily Z. Kalashnikov, Sergey I. Maslennikov
and Vitaly G. Tarasov

24.1 INTRODUCTION

Scallops are the most intensively consumed and fished bivalve molluscs in Russia. There are more than ten scallop species found within the seas of the Russian Federation. The best known is the Yesso scallop, *Mizuhopecten yessoensis*, also referred to as the Ezo scallop, giant scallop, Japanese scallop, Russian scallop, Primorsky scallop and common scallop. For a long time these molluscs have been the focus of traditional fishing in the coastal waters of the Sea of Japan, Southern Sakhalin, and the Southern Kurile shoal. Commercial scallop beds, averaging 4,000 tons per year, can be found in the Barents Sea (*Chlamys islandica*), the Bering Sea (*C. behringiana*), the Kurile Islands and northern Primorye (*C. albida* and *C. chosonica*), and in Peter the Great and Posjet Bays of the Sea of Japan (*C. farreri*). This chapter reviews the biology and ecology of eight scallop species from the Russian part of the northern Pacific Ocean. Fishery statistics and typical technologies used at these commercial aquaculture farms are also presented.

24.2 TAXONOMIC STATUS

According to (Kafanov 1991; Kafanov and Lutaenko 1998) there are eight species of Pectinidae in the Russian part of northern Pacific Ocean. Their taxonomic status follows:

Class Bivalvia Linné, 1758

Order Pectinida H. Adams et A. Adams, 1857

Family Pectinidae Rafinesque, 1815

Genus *Chlamys* Röding, 1798

Chlamys (*Chlamys*) *albida* Arnold, 1906 (ex Dall, MS)

Until recently, this species was confused with *C. islandica* (Müller, 1776)

C. (C.) asiatica Scarlato, 1981

C. (C.) behringiana (Middendorff, 1849)

C. (C.) chosonica Kuroda, 1932

Until recently, this species was confused with *C. rosealba* Scarlato, 1981

C. (Azumapecten) farreri (Jones et Preston, 1904)

Until recently, this species was confused with *C. farreri nipponensis* Kuroda, 1932 or *C. nipponensis* Kuroda, 1932
C. (Swiftopecten) swifti (Bernardi, 1858)
 Genus *Delectopecten* Stewart, 1930
Delectopecten randolphi (Dall, 1897)
 Genus *Mizuhopecten* Masuda, 1963
Mizuhopecten yessoensis (Jay, 1857)

24.3 BIOLOGY AND ECOLOGY

24.3.1 *Chlamys albida* (Common names: white scallop and commercial scallop)

Chlamys albida is a widespread, high-boreal, Pacific species (Fig. 24.1). It occurs from Middle Primorye (Lutaenko 1999) up to the northern part of the Sea of Japan (Tatar Strait), along the northern coastline of the Sea of Okhotsk, and near the Kurile (Paramushir and Iturup), Commodore and Aleut Islands. It lives in muddy-sands with pebbles at depths between 36–398 m (Scarlato 1981). Environmental ranges are typical for near-bottom waters: temperature -0.79 to 4.79°C , salinity 33.05–33.43‰ and oxygen concentrations from 5.67 to 6.40 mg L⁻¹ (Myasnikov 1985). At Kurile, white scallops were more frequently fouled by sponges *Mycale adhaerens* and *Myxilla parasitica* and rarely inhabited by various hydrozoa, barnacles, bryozoa, algae, polychaetes, actinias and juveniles of bivalve molluscs (Myasnikov 1986).

The growth rates of scallops from different regions of the Kurile Ridge differ greatly from each other (Silina and Pozdnyakova 1986) but approximately equal and high rates of linear growth (up to 13.5 mm yr⁻¹) are observed in all regions during the first three years (Fig. 24.2; Table 24.1). After this age, the most intensive growth is observed in scallops living along the Sea of Okhotsk side of Onkotan Island, where shell growth is up to 18 mm·yr⁻¹. Minimum shell growth was observed at Simushir Island (middle Kuriles) where the annual rates did not exceed 13 mm yr⁻¹ and in Pacific Ocean waters of Onkotan Island. According to Zolotarev (1979) these molluscs have three strongly pronounced stages of linear growth: juvenile, mature and senile. For *C. albida*, juvenile or fast growth stage finishes when the age of puberty is reached. The next stage (mature) is limited to 10 years. Senile stage starts at 10 years when annual shell growth does not exceed 0.5–1.5 mm. Scallops reach marketable size (60 mm) at about 5 years (Table 24.1).

Scallop weights also change irregularly with age. In scallops up to 50–60 mm, weight increases by equal rates. After this size, the rate of weight increase in scallops inhabiting the Sea of Okhotsk side of Onkotan Island differs from that of scallops from Pacific Ocean waters. Maximum weight increases (up to 23 g yr⁻¹) are observed at the age of 5 years.

Figure 24.1. Natural habitat of the White scallop *Chlamys albida* Arnold, 1906 (ex Dall, MS) (by Scarlato 1981). A – map showing known commercial assemblages.

12.5			77.4 $\pm$ 1.2

Figure 24.2. Growth rates of the White scallop *Chlamys albida* at Okhotsk Sea and Pacific sides of Onekotan Island, Kurile Islands (by data of Myasnikov, Kochnev 1988). A - Total shell height, mm. B - Annual shell growth, mm.

According to Myasnikov (1988), the size range in the population of *C. albida* from the northern part of the Sea of Okhotsk includes scallops with shell heights between 18–93 mm (average of 68 mm) but individuals within the size of 70–80 mm (about 40%) were most common. The average shell height correlates with depth. As depth increases from 50 to 125 meters the average shell height increases from 41 to 73 mm. At depths of over 125 m, average shell heights decreased to 62 mm.

The maximum age of these scallops does not exceed 28–30 yr. The age of sexual maturity is 3 to 5 years with shell heights between 40–70 mm. The sex ratio (male to female) changes from 0.6:1.0 to 2.0:1.0. At North Kuriles, mass spawning in population starts in June (Myasnikov and Kochnev 1988).

There are four commercial concentrations of *C. albida* along the southern and northern coastlines of Northern Kurile Islands (Sea of Okhotsk side and Pacific Ocean side), at Simushir Island and in the Northern part of the Sea of Okhotsk (Myasnikov and Hen 1990; Myasnikov et al. 1992).

24.3.2 *Chlamys asiatica* (Common name: Asiatic scallop)

Chlamys asiatica is a high-boreal, Asian-Pacific species (Fig. 24.3). The Asiatic scallop occurs on Kurile Island, on the eastern coast of Kamchatka Peninsula and in the

Bering Sea (Anadyr Bay). It lives in sandy substrates mixed with shingle and muddy sands at depths between 80–120 m (Scarlato 1981). It was rarely found in its natural habitat.

24.3.3 *Chlamys behringiana* (Common name: Bering Sea's scallop)

Chlamys behringiana is a widespread, high-boreal, Pacific species (Fig. 24.4). It occurs within the Sea of Okhotsk at Sakhalin and Aniva Bays, the Strait of Laperuz, the southern and eastern waters of Kamchatka Peninsula, and the Kurile Islands (Paramushir and Shikotan). It is also found in the Bering Sea and in the Arctic Ocean at the southern part of the Chuckchee Sea and Sea of Beaufort. It is found at depths between 24–200 m in muddy sands mixed with shingle and gravel and in gravel with pebbled substrates (Scarlato 1981). Environmental ranges have been reported by Myasnikov (1985) for temperature (0.79 to 4.79°C), salinity (33.05–33.43‰) and oxygen concentrations (5.67 to 6.40 mg L⁻¹). Bering Sea's scallops are often inhabited by hydroids, *Eunephthya* sp., and ascidians, *Pyaridae* sp. (Myasnikov 1986).

According to Buyanovsky (1999), larger scallops are observed at Karaginsky Island (size: 72.7 mm, age: 10–15 yr) and at Olyutorsky Bay (size: 83.3 mm, age: 20–25 yr). After these ages, shell height does not change. Higher growth rates in scallops from Olyutorsky Bay are probably linked to the more intensive water exchange via the main branch of Kamchatka Current.

Figure 24.3. Natural habitat of the Asiatic scallop, *Chlamys asiatica* Scarlato, 1981 (Scarlato 1981).

Figure 24.4. Natural habitat of the Bering Sea's scallop *Chlamys behringiana* (Middendorff, 1849) (Scarlato 1981).

The maximum age of the Bering Sea's scallop is 35 years old but most of the older population is 25–28 years old. The most intensive growth period is observed during the first two years and can be as high as 15 mm yr^{-1} . Between the ages of 3–6 yrs, the shell typically grows $4.2\text{--}11.5 \text{ mm yr}^{-1}$. Then, at the age of sexual maturity, growth rates decrease considerably until they reach $1.6\text{--}1.2 \text{ mm yr}^{-1}$ in 10-year-old scallops (Silina and Pozdnyakova 1991). Scallops reach marketable size (60 mm) in about 6 years (Table 24.1). Scallop weights increase almost in proportion to their age (Buyanovsky 1999).

24.3.4 *Chlamys chosonica* (Common names: Pink scallop and White-pink scallop)

Chlamys chosonica is a low-boreal, Asian Pacific species (Fig. 24.5). It occurs in the Sea of Japan along the Primorye coastline, at the western Sakhalin Island and the north western part of Hokkaido Island, in waters of the small Kurile Ridge and at Iturup Island. Pink scallops are found at depths between 13–2,030 m in muddy sands mixed with shingle and gravel and sometimes in sand or shell-rock substrates (Scarlato 1981). The pink scallop is a eurybiontic species occurring at temperatures ranging from -0.09 to 13.03°C , salinities ranging of $33.34\text{--}34.15\text{‰}$ and oxygen concentrations ranging from 5.49 to 7.49 mg L^{-1} (Myasnikov 1985). Along the coast of Northern Primorye, pink scallops are mainly colonised by the gastropod *Vetulina* sp. (Myasnikov 1986).

Figure 24.5. Natural habitat of the Pink scallop, *Chlamys chosenica* Kuroda, 1932 (Scarlato 1981). A – map showing known commercial populations.

According to Silina and Pozdnyakova (1990), the population from the northern Primorye is characterised by scallops with shell heights up to 90 mm. The size distribution is a uni-modal curve with most individuals measuring 68–81 mm (peak at 77–76 mm). The maximum age of scallops is 22 years but most of the population is 11–12 years old.

The most intensive time of growth is observed within the first two years and can be up to 16 mm yr⁻¹. Between the ages of 3 to 6 years the shell grows by 5.2–10.8 mm yr⁻¹. At the age of sexual maturity, growth rates decrease to 2.5–1.0 mm yr⁻¹ in 10-year-old scallops. Pink scallops reach marketable size (60 mm) in about 6 years (Table 24.1). In 9 to 14 year old scallops, with an average shell height of 70–79 mm, the muscle weight ranges from 7.4–10.4 g. In four years, from 10 to 14 yr, muscle weight increases by not more than 25% and shell weight increases by least by 50%. At the same time, the muscle comprises 20–25% of the total weight of the mollusc whenever shells comprise 44–52%.

The sex ratio (male to female) in these populations is approximately 1.0:1.2. The domination of females (55%) implies stable status. Spawning of the population takes place in the first half of summer (Silina and Pozdnyakova 1990).

24.3.5 *Chlamys farreri* (Common names: Japanese scallop, Chinese scallop, Farrer's scallop, Akazara scallop)

Chlamys farreri is a subtropical, Asian-Pacific species (Fig. 24.6). In the Sea of Japan it is widely distributed along the southern coasts. This is the northern border of its natural habitat. It also occurs at Middle Primorye and Japanese Island at depths from 0.5 to 24 m (Scarlato 1981). The scallop is mainly found in gravel and pebbled habitats. Frequently these scallops form many-tiered reefs in the rocks and oyster banks. Settlement densities can vary between 150–180 specimens m⁻² (in reefs) at depths of 1.5–2.5 m. At other depths, their density decreases to 5–10 specimens m⁻². This species occurs at a temperature range of 19–22°C and a salinity range of 32–34‰.

This species is a candidate for mariculture and fishery in East Asian countries (Wang and Shieh 1991). In Russia, the Japanese scallop is one of the most prominent species for commercial fishing and mariculture (Bregman 1982; Afreichuk 1992a).

According to Afreichuk (1992a), the population of *C. farreri* from Posjet Bay includes scallops with shell heights of up to 112 mm but most individuals measure 70–80 mm. The maximum age of this species is 9 years but most of the population is three (35%) or four (27%) years old. After age 6, natural mortality increases and results in only 12% of population being older than 6 years.

The most intensive growth period is observed in the first three years and can be as high as 19 mm·yr⁻¹. Between the ages of 4 and 7, the shell grows by 5.8–11.5 mm yr⁻¹. After this, growth rates decrease (Afreichuk 1992b). These scallops reach marketable size (72 mm) in about 3–4 years. At that time the muscle weighs about 5.5 g. The muscle weight of a 5-year-old scallop with average shell height of 90 mm is 11 g. In total, the muscle comprises 12–14% of the total weight of the scallop and the shells amounts to 63% (Afreichuk 1990).

The age of sexual maturity is 2 years old with shell heights typically 40–45 mm (Table 24.2). The approximate sex ratio (male to female) in population is 1:1.36. At Posjet Bay spawning of the population starts at the end of June when the temperature of near-bottom waters approaches 16°C. The mass spawning (average 65 days) begins in the middle of July at temperatures of 18–20°C and ends at the end of August or early in September (Afreichuk 1992a).

Figure 24.6. Natural habitat of the Japanese scallop, *Chlamys farreri* (Jones and Preston, 1904) (Scarlato 1981).

Table 24.2

Shell height (mm) of different ages of Japanese scallop *Chlamys farreri* at southern part of the Sea of Japan (Bregman 1982), mm $\pm$ s.d.

Age (years)	1	2	3	4	5
Shell height (mm)	2.70 $\pm$ 0.96	4.30 $\pm$ 1.50	5.85 $\pm$ 0.90	7.00 $\pm$ 0.96	7.80 $\pm$ 0.96

At Peter the Great Bay larvae occur in plankton during the warmest months (July and August) at water temperatures between 15–20°C (Kas'yanov et al. 1980). The maximum density of larvae occurs in shallower bights between 5–7 m (Afreichuk et al. 1988). The period of settling on hard and fibrous substrate (depths up to 23 m) continues from the middle of July to early August. The optimal depth for spat collection is 5–8.5 m (Gabaev 1988). The density of juvenile settlement on collectors can reach a maximum of 229 and an average of 48 specimens m⁻² (Afreichuk et al. 1988; Gabaev 1990b). The morphology of larvae and larval shell structure were described by Kulikova et al. (1981).

24.3.6 *Chlamys swifti* (Common name: Swift's scallop)

Chlamys swifti is a low-boreal, Asian-Pacific species (Fig. 24.7). It is distributed along the southern coasts of the Sea of Japan, in Western Sakhalin, Hokkaido and northern waters of Honshu Island. In the Okhotsk Sea Swift's scallops have been found in southern Sakhalin (Aniva Bay) and in shallow waters of South Kurile Shoal. The scallop mainly inhabits the gravel, pebbled and shell areas at depths of 2–143 m (Scarlato 1981). This species occurs within a temperature range of 9 to 22°C and a salinity range of 32–34‰.

According to Ponurovsky (1982) and Ponurovsky and Silina (1983), the population of *C. swifti* from the Northern Primorye is characterised by scallops with shell heights up to 121 mm, but individuals measuring between 65–90 mm predominate. The maximum age of scallops is 13 years, but the majority of the population is five years old.

Swift's scallops grow throughout their lifetime. However, the greatest growth period is observed during the first three years after settling on the bottom and can be as high as 21–26 mm yr⁻¹. After 4 years old, linear growth rates decline and are only 1.0 mm yr⁻¹ in 8-year-old individuals (Ponurovsky 1977; Ponurovsky and Silina 1983). The highest growth rates were found in regions of the Sea of Japan, Petrov and Putyatin Islands, and Vostok Bay (Table 24.3). These areas are more favourable for intensive growth of Swift's scallop (Ponurovsky 1982).

The sexual maturity is reached at 3 years when shell heights are 50–70 mm. The approximate sex ratios (male to female to hermaphrodite) in the population are 1.0:0.67:0.02 (Denisova 1981). By the age of 3, males predominate (86.3%) in the population. Later, the percentage of males declines. By the age of 10, females predominate (81.2%) the population.

At Peter the Great Bay and Bousse lagoon (southern Sakhalin Island) larvae are abundant in the plankton from August to September in water temperatures between 15–20°C. The maximum density of larvae occurs in near-bottom waters at depths of 10–20 m (Kas'yanov et al. 1983). The morphology of larvae and larval shell structure were described by V. A. Kulikova with co-authors (1981). The optimal depth for spat collection is greater than 15 m (Gabaev 1988).

Figure 24.7. Natural habitat of the Swift's scallop, *Chlamys swifti* (Bernardi, 1858) (Scarlato 1981).

24.3.7 *Delectopecten randolphi* (Common name: Randolph's scallop)

Delectopecten randolphi is a widespread North Pacific species (Fig. 24.8). It is found in the Sea of Japan at Posjet Bay, Peter the Great Bay, and the eastern coastline waters of Honshu Island (Sagami Bay). It is also found in the Okhotsk Sea along eastern and western coastlines and in the Bering Sea along the eastern coastline. The Randolph's scallop inhabits muddy areas at depths of 418–3,080 m (Scarlato 1981). Its temperature range is 0.2–2.5°C. The largest specimen known had dimensions of 23.5 x 27.0 mm and was found in Peter the Great Bay.

24.3.8 *Mizuhopecten yessoensis* (Common Names: Yesso scallop, Ezo scallop, Giant scallop, Japanese scallop, Russian scallop, Primorsky scallop and Common scallop)

The Yesso scallop, *Mizuhopecten yessoensis*, is a low-boreal, Asian-Pacific species (Fig. 24.9) with the highest commercial value of all the Pectinidae. It is found along the northern coastline of the Korean peninsula, the coastline of Primorye, near the shores of the Sakhalin islands, South Kuriles and Hokkaido and on the northern coastline of Honshu Island (Scarlato 1981).

Figure 24.8. Natural habitat of Randolph's scallop, *Delectopecten randolphi* (Dall, 1897) (Scarlato 1981).

Figure 24.9. Natural habitat of the Yesso scallop, *Mizuhopecten yessoensis* (Jay, 1857) (Scarlato 1981 with additions). A and B – maps show known commercial assemblages at Sakhalin and Kunashir Islands.

24.3.8.1 Total populations and biomass

The most exhaustive studies of the Yesso scallop were completed along the coasts of Primorye by Razin (1934), Biryulina and Rodionov (1972), Markovskaya (1951), Bregman (1979), and Kalashnikov (1986, 1991).

In 1932, an estimated 40 million scallops inhabited some of the 16,000–17,000 hectares along the coast of Primorye. Between the 1940's-1960's, the scallop population in most areas decreased and in some places completely disappeared. From 1932 to 1959, the scallop stocks in Peter the Great Bay had reduced thrice. In the following decade, the abundance remained almost the same at 5,703 million scallops on 906 hectares with a biomass of 1,708 tons (Biryulina and Rodionov 1972).

At the same time, a significant drop in the abundance of scallops was observed in the northern areas of Peter the Great Bay (Olga Bay) where the scallop population in 1932 was four times as high as it was in 1975 (Silina and Bregman 1986). According to Skalkin (1971), the biomass in Aniva Bay (southern Sakhalin) in 1969 was twice as low as compared to 1961–1962. The scallop populations became ten times as low in Terpenie Bay (northern Sakhalin) and some areas of the Kuriles. Most investigators believe that intensive industrial fishing caused the overall drop in scallop stocks. At the present time, commercial reserves of wild Yesso scallop along the coast of Primorye are exhausted due to overfishing during the last decade.

24.3.8.2 Distribution in Primorye

The Yesso scallop was widely distributed in southern and middle Primorye where it is found in bays and coves and forms aggregations at depths between 6–30 m. These scallops were an object of traditional catching until the beginning of 1970's. The map (Fig. 24.10) shows the locations of existing and potential plantations sites for bottom cultivation of this scallop species. Commercial populations were well known in Bays of Posjet, Ussuri, Amur, Vladimir, Vostok and Strelak. The average density of settlements on bottom grounds increased from 0.05 to 1.0 specimen m^{-2} (average 0.1 specimen m^{-2}). Average individual biomass was 0.2–0.4 kg. At the present time, the average density does not exceed 0.001 specimen m^{-2} at sites described by other authors.

24.3.8.3 Distribution over depths

In the shallows, the Yesso scallop occurs between depths of 0.5–1.0 m in small inlets protected from wind and waves. Minimum depth corresponds to the winter time water level under the ice cover. Most of the scallops were found in the range of 4–10 m in closed inlets and at depths between 20–25 m in open and relatively deep-water sites of bays and inlets. According to Razin (1934) this species is typically found between 14–30 m on the open coastline of Primorye, however some specimens are found at 48 m.

Most of the scallops were found along the coastline at a depth of 20–25 m near rugged shores. This is apparently due to the corresponding range of spat settlement in the region, i.e., underwater rocks are substrate carriers for attaching scallop larvae. In Peter the Great Bay, scallops were recorded at a maximum depth of 82 m (Scarlato 1981).

24.3.8.4 Age structure of scallop settlements

Biologists believe that this species does not live more than an average of eleven years (Tibilova and Bregman 1975) with a typical life expectancy ranging from 7 to 9 years (Makarova 1985). The most extensively studied populations in Primorye have no 1–2 year old specimens. Eleven-to-twelve year-old scallops are frequent but older specimens are rare (see Table 24.4). In some settlements, 70 percent of the individuals range in age from 8 to 16 years. Generally, the age structure of the scallop population of various

Figure 24.10. Locations of existing and potential plantations for bottom cultivation of the Yesso scallop *M. yessoensis* in Primorye.

regions reflects the randomness of replenishment and presence of abundant and non-abundant generations (Fig. 24.11).

24.3.8.5 Scallop growth

Fertilised eggs (average 60–70 micrometers in diameter) develop into larvae, which settle onto substrates (shell averages 260–285 μm) in 20–40 days, depending on temperature. Definitive development of scallops terminates on the substrate. The scallop detaches from the substrate in 3–4 months when the shell height is 10–30 mm. Subsequent scallop growth rate depends on temperature, feeding, water exchange, and many other conditions on the sea floor.

Table 24.4

Age composition of Yesso scallop settlements at Peter the Great Bay (Silina and Bregman 1986). Number of specimens from respective age groups.

Region	1-2	3-4	5-6	7-8	9-10	11-12	13-14

Melkovodnaya Inlet	2	13	20	11	6	5	1
Olga Bay	--	--	1	23	16	7	1

The scallop shell grows isometrically to retain its initial form. Makarova (1985) calculated the general equation for the linear growth rate of the Yesso scallop:

$$H_t = (160.92 \pm 18.7) \cdot (1 - e^{(-0.378 \pm 0.04) \cdot t}), \quad (1)$$

where H_t is the shell height in mm and t is scallops age in years.

The scallop grows at temperatures ranging from -2°C to 26°C. The optimal growth temperature is 4–6°C. In Primorye, the temperature optimum occurs in May-June and in September-October (Silina and Pozdnyakova 1986). Within the initial three years, the scallop height reaches 90–110 mm and then its growth slows exponentially (Table 24.5). The largest individuals occur at depths of 20 m in populations located on silty-sandy soils with good water exchange and relatively stable temperatures. These specimens reach 190–195 mm shell height or longer at the age of 16 and older. In the South Kurile shallows, specimens older than 20 years with shell heights of 220 mm are found (Skalkin 1966). In shallow silty inlets, scallops seldom exceed 150 mm and live for not more than 10–12 years. In Posjet Bay, we recorded the largest scallop specimen, whose dimensions were as follows: shell height 222 mm, length 202 mm, and width 37 mm. Scallop weights vary proportionally to its linear dimensions (Fig. 24.12; Silina and Pozdnyakova 1986). The proportion of muscle in scallop total mass amounts to 10–18% in various settlements of Peter the Great Bay (Belogradov 1981).

24.3.8.6 Sex structure of settlements

The average (male to female) sex ratio within populations is 1.0:1.0. Hermaphrodites were rarely observed (i.e., not more than 0.3–0.4% of all cases; Bregman 1979). In these populations, males dominated in younger generations and females dominated in older ones. By age 1–3 the sex ratio was 2.0:1.0, by age 5–6 it was 1.9:1.0 and by the age of 7–8 the sex ratio was 1.0:1.9. This could be due to either sex specific different death rates or hermaphroditism.

Figure 24.12. Relationship between Yesso scallop weight and shell height in various settlements in Peter the Great Bay. Numbers represent scallop age in years. (From Salina and Pozdnyakova 1986)

24.3.8.7 Replenishment

Scallop populations replenish annually owing to spawning, subsequent development of larvae in plankton, their settling on substrate and juveniles' transition to free life on the seabed.

24.3.8.8 Spawning

Spawning in scallop populations starts at temperatures ranging from 7–9°C. (Belogrudov 1981). In the waters around Primorye, spawning begins in the middle of May and spawning ends at the end of June. Spawning begins in shallow waters of

southern regions. As the seawater warms up individuals from the deeper and more northerly settlements begin to spawn. Absolute fertility varies from 25–30 to 180 million eggs (Yamamoto 1964) depending on age and size.

24.3.8.9 Larvae morphology

The morphology of larvae and larval shell structure of three widespread scallops: Yesso scallop *M. yessoensis*, Japanese scallop *C. farreri* and Swift's scallop *C. swifti* have been described by Kulikova et al. (1981). All of the larvae are of triangular form and the anterior end is the apex of the triangle. The larvae are inequivalve. The umbos are low, rounded and poorly defined. The taxodonte hinge has several teeth at each side of the hinge line. The central hinge area is undifferentiated. Some specific characteristics were distinguished among the scallop larvae of Peter the Great Bay. The main differences are in the shell form, umbo form, shell size, and number of teeth at each side of the hinge line (Kulikova et al. 1981).

24.3.8.10 Development in plankton

The duration of larval growth in the plankton lasts from 20 to 40 days (Kas'yanov et al. 1980). Current-induced distribution disseminates larvae to create new local settlements. Plankton surveys (Belogrudov 1981) show that larvae can form dense concentrations in Posjet and Peter the Great Bays over several square kilometers. In that case, higher densities are noted at areas with abounding adult scallops. In bonanza years, larval density reached 200–300 specimens per cubic meter in the closed inlets and at the same time, it did not exceed 20–30 specimens per cubic meter in the adjacent open inlets and bays. Long-term studies in Posjet Bay show the absence of direct spatial relations between parents and new scallop generations.

On the eve of scallop cultivation, the number of sexually mature specimens in Minonosok Inlet in 1972 was 70,000. Ten years later, the number has increased up to 650,000 because of sowing culture (Fig. 24.13). The number of annually collected spat showed instability of larvae settling throughout all periods. Nor was there any sign of increases in the number of spat during the year. Apparently, the parent-larvae relationship was indirect because of great dilution of larvae pool by the water mass (Kalashnikov 1986). Water exchange with adjacent bodies of water (about 10% of waters every day is replaced by tidal) disturbed the parent-larvae relationships.

A comparison of the age composition (Fig. 24.13) and the results of spat collection in various bays and inlets showed that intensity of replenishment changes asynchronously. Bonanza generations in one bay do not necessarily correspond to the same in another bay. For instance in 1980, the lowest spat settling rates (2–20 specimens per collector) were noted in Posjet Bay, but in Vostok Bay the collectors recorded 400–500 specimens each. It is of interest to note that during that year, red tides were absent in Vostok Bay but observed in Posjet Bay. However, these distinctions were also noted in other bays without red tides, and this suggests that the intensity of replenishment is a local characteristic.

Figure 24.13. Dynamics of spat collection (A) and size of the Yesso scallop population of Minonosok Inlet (B). (From Kalashnikov 1991)

24.3.8.11 Migration behaviour

Yesso scallops can freely move along the sea floor. The mechanism of reactive movement of freely living scallop is widely known (for example: Dautov and Karpenko 1983). Researchers have noted random movement in natural conditions or individual scallop behaviour in aquarium. These observations support the idea that the scallop is a migrating species. However, the observation that populations are present for many years in specific sites shows that ability of scallops to migrate is limited.

24.3.8.12 Risk factors

24.3.8.12.1 Abiotic factors

Survival rates of pelagic larvae at metamorphosis depend on water temperature (ranges for survival is 5–20°C, with an optimum at 10–15°C), salinity (30–40‰, optimum at 33‰), density (optimum 8 specimens mL⁻¹), quantity and composition of food and on the abundance of predators (Belogradov 1973; Bregman and Guida 1983; Chan 1989). At attachment, mortality is mainly caused by the absence of suitable substrate and intolerance to changing environments (Yamamoto 1964; Belogradov 1973). Bregman and Guida (1983) reported that the number of attached juveniles resulted from only 5–8% of all fertilised eggs. Settling on the bottom is the next critical period in the life history of the scallop and here the mortality increases sharply. According to Yamamoto (1964), only 5–10% or sometimes none of the settled juveniles survive. Golikov and Scarlato (1970) reported that only 4% of the settled juveniles survived as long as 6 months. Only Golikov and Scarlato (1970) have reported on the mortality of older scallops. These researchers conjectured that after 6 months the quantity of survived scallops decreased gradually. Moreover, they noted that winter was the period during which the highest mortality of scallops occurred off the north western coastline of the Sea of Japan. In contrast, in Honshu Island, the most difficult season for scallop survival is summer and early autumn when water temperature increases to above 15°C (Yamamoto 1960).

Recent investigations (Silina 1996) also show the highest mortality when scallops were less than 2 years. Mortality of 2 to 5 year-old scallops is minimal. By 6–7 years of age (probably the beginning of the senile period of scallop development) and upwards to 9–10 (transition to the old-aged stage) scallops mortality increased sharply.

24.3.8.12.2 Storms

Storms are another factor, which cause mass mortalities of scallops in coastal shallow settlements. Depending on local topography, storms can increase settlement dispersion over vast flat areas or make them denser at the foothills of cliffs. In either case, a considerable number of scallops are buried under moving soil. Near shallow coasts, particularly beaches, the majority of scallops die in storm debris. Even small storms deform settlements but the loss is usually compensated by annual replenishment. While the typhoons (annual frequency about 50%) are natural calamities for the benthic coastline

populations, including the scallop, they destroy most of the species around open waters at 20 m deep. By counting the number of shells in the breaker zone of only one beach following typhoon "Ellis" in 1983, researchers revealed the simultaneous death of 10,000 specimens of different ages. In a similar count in 1986 after typhoon "Vera", we discovered as many as 72,000 specimens in debris (Kalashnikov 1984). The joint effect of various factors on the sea floor populations shows perennial changes in density of artificial scallop populations, which regularly declined in all cases during the first cultivation season. The decline was greater in more open and unprotected waters (Fig. 24.14; Kalashnikov 1985).

24.3.8.12.3 Predators

The first hours and days on the sea floor after the scallops become one year old (shell height about 30 mm) appeared to be the most dangerous. During this period, natural death is maximal and young scallops are preyed upon by various starfish species such as *Asterias amurensis* Lütken, which can grow up to 165 mm (radius) and weigh up to 450 g. Another species, *Distolasterias nipon* (Döderlein) is even larger growing up to 250 mm with an average weight of 1,000 g. These starfish species attack scallops of the same or younger ages. The one-time ration of one starfish increases from 1 up to 8.5 g of fish and annually amounts to 400–450 g (Biryulina 1972). In view of the great abundance of these predators (density can be up to 15 specimens m^{-2}), the damage to scallop populations can be considerable. The death rate of young scallops located in super dense aggregations (over 100 specimens m^{-2}) in which predators temporarily eat only scallops is especially high.

When storms are so strong that they reach the sea floor scallops become weaker and readily accessible to predators. The joint effects of storms and starfishes have destroyed an artificial scallop settlement (about two hectares) with a population of over 200,000 specimens. Under stable conditions, starfish and scallops were noted to co-exist when they occupied a single habitat for several years in succession. Generally, however, the number of cultivated molluscs declines more in sites where starfish are more abundant. Sowing spat are also preyed upon by various benthic fishes such as flounders and bullheads. Other predators of sown seed and adult scallops are of lesser importance but nevertheless pose a threat to small seed and juveniles. These include the octopuses, king crabs, *Paralithodes camtschatica* (Tilesius), and hermit crabs (Kalashnikov 1986). Crabs predate mainly on seed scallops present in large numbers. For example, during seasonal migrations, crabs can greatly denude newly seeded grounds. Some predatory gastropod molluscs pose a threat to both juveniles and adult scallops. Belogradov (1973) reported that the drilling Muricidae gastropod *Boreotrophon candelabrum* (Adams et Reeve) and *Tritonia japonica* (Dunker) could attack and eat the scallops. At natural population levels, 14–27% of adult scallops had drilling marks on the shells. Gabaev and Kolotukhina (1999) reported that two-year scallops (shell height up to 73 mm) in the cages are preyed upon the gastropod *Nucella heyseana* (Dunker).

Figure 24.14. Density of Yesso scallops plantations in Posjet Bay (number m⁻²). 1 = closed lagoon; 2 = protected island terrace; 3–6 = sites of open waters. (From Kalashnikov 1991)

24.3.8.12.4 Parasites

In comparison to other cultured bivalves, such as oysters and mussels, little is known about the parasites and diseases of scallops. Epizootic diseases, like those that have devastated the oyster culture industry in parts of the world, have not been encountered by the scallop culture industry. The relative lack of information on parasites and diseases in scallops may be attributed to less intensive cultures and comparatively fewer investigations. Infection of scallops by parasites is low, as the parasitic fauna is scarce and includes only a few potentially pathogenic species. Mass scallop deaths caused by parasites have never been recorded. There are only 17 parasites and commensals now associated with scallops (Kurochkin et al. 1986; Kovalenko 1990; Plyusnin 1990; Rakov 1990; Didenko 1996).

Sirolopidium zoophthorum Vishniac, 1955 (Lagenidiales)

This fungus was found in 1972 in juveniles at a scallop farm in Posjet Bay.

Myxosporidia gen. sp. (Myxosporidia)

Local pestholes, which probably were caused by unknown Myxosporidia, were noted at a scallop farm in Minonosok Inlet (Posjet Bay) in April of 1996.

Perkinsus sp. (Sporozoa)

They were unknown until 1979 when a spherical cyst (0.2–0.3 mm in diameter) of *Perkinsus* sp. was found in 86% of discovered scallops (intensity of invasion by 1–2 cysts). Occasionally they can pose serious threats to scallop spat. Conceivably it was introduced with scallop seed from Aomori prefecture, Japan.

Pectenita golikowi Jankowski, 1973 (Ciliophora)

Almost all scallops are affected by this endoparasitic infusoria. Intensity of invasion is several tens of individuals within a scallop's intestine. Pathogenic effects on the host are unknown.

Trichodina pectenis Stein, 1974 (Ciliophora)

See below.

Trichodina sp. Stein, 1974 (Ciliophora)

These two species of endoparasitic infusoria were described in the mantle of Yesso scallops. Intensity of invasion is 20–100% and by several tens of specimens. Pathogenic effects on the host are unknown but probably caused by a secondary parasite.

Cliona sp. (Porifera)

This drilling parasitic sponge causes extensive invasions of up to 70% on lower (right) valve and up to 10% on upper (left) one.

Hirudinea gen. sp. (Hirudinea)

Leeches were found in the mantle on isolated instances.

Podocotype spp. (Trematoda)

Approximately 1% of all scallops are affected by trematode metacercaria, which were found in various tissues (including adductor muscle). Intensity of invasion is only one specimen per scallop.

Anisakidae gen. sp. (Nematoda)

Larvae of these nematodes were found in the digestive system on isolated instances.

Ohridiidae gen. sp. (Nematoda)

Ohridiidae affects approximately 73% of scallops. Larvae of these nematodes were found in the mantle with intensity of invasion up to 17 specimens per scallop.

Polydora ciliata (Johnston, 1838) (Polychaeta)

This widespread and well-known drilling polychaete is responsible for loss of market quality among cultivated and natural Yesso scallops. It has a larger effect on the upper (left) valve. The burrows excavated by *Polydora* in scallop shells cause unsightly blisters containing compacted mud. Approximately 75% of scallops have wormholes and blisters. Since 1974 infestation of scallop shells by the boring polychaetes has increased as siltation of the bottom increases (Silina et al. 2000).

Polydora websteri Hartmann, 1943 (Polychaeta)

Burrows and blisters of this species are indistinguishable from ones of *P. ciliata*.

Dodecaceria concharum Oersted (Polychaeta)

These drilling polychaete have wormholes similar with ones of *Polydora*. They can use old holes created by other polychaetes and sponges.

Herrmannella longicaudata G. Avdeev, 1975 (Copepoda)

These small (maximal length up to 2.2 mm) cyclopoid copepods were found in approximately 73% of Giant Yesso and Swift scallops. Pathogenic effects on the host are unknown even in the case of great abundances. Average intensity of invasion by commensals is nine specimens in the mantle.

Odostomia fujitani Yokogawa, 1927 (Gastropoda)*O. (Evalea) culta* Dall et Bartsch, 1906 (Gastropoda)

These small (maximal shell height up to 5 mm) littoral gastropods often prey on various bivalves as temporary parasites. Gastropods feed with using a long proboscis, which they introduce between shell valves.

24.3.8.12.5 Bacterial contamination

Numerous species of bacterial contaminants have been identified from cultivated scallops (Table 24.6; Avdeeva and Filipchuk 1988, Kovalenko 1989, Plyusnin 1990, Plyusnin and Cherkashin 1991, Kovalenko 1994). A total of 29 species were identified from scallop farms. Most of them are Gram-negative bacteria (22 species). Some of them (e.g., *Aeromonas*, *Vibrio* and *Pseudomonas*) are potentially pathogenic in situations where environmental culture conditions are poor.

24.3.8.12.6 Epibionts

Natural and farmed scallops are an excellent substrate for the settlement of many other organisms (collectively called fouling communities). Marine organisms that occur on scallop shells may be competitors for space and food. Epizoans may also reduce water flow and food accessibility.

24.4 FISHING AND AQUACULTURE

24.4.1 Fishing

24.4.1.1 History

Paleontological and archaeological studies reveal that the people inhabiting the coastal areas of the Far East had, from time immemorial, used marine organisms, including bivalve molluscs, to develop their national economy (Krasnov et al. 1977). A unique Yankovsky culture of shell mounds has been found in many regions (Okladnikov and Derevyanko 1973) dating from the Paleolithic age (25,000–30,000 years BC). Numerous shell concentrations suggest that the inhabitants of the coasts of Sakhalin, the Kuriles, Japan, Primorye and Korea preferred gastropods, mussels, and scallops.

We still do not know how ancient people obtained the scallops. Without any suitable gear and boats they may have only been able to collect them from storm debris. The subsequent history of scallop fishing in Primorye is known from descriptions by pioneer explorers of Ussuri Region, including N. M. Przevalsky and V. K. Arseniev. Russian merchants recall that during the last century Yesso scallops were exported as seasoned meats (muscles). Scallops were fished in Vladimir Bay and sold to China. The second half of the 19th century saw further development of scallop fishery along with the settlement of the Russian Far East. This was supported by its value and by the boundless demand on the local market. By the 1920's, the price for Yesso scallop in Vladivostok was as high as 10 rubles per 100 molluscs. During that time, they fished scallops in shallow bights using one-or-two-pronged lances and scoop nets (while watching it from the surface through a glass-bottom box), primitive dredges and cords (Razin 1934).

Table 24.6

24.4.1.2 Fishing gear

Dip-nets were used to fish Yesso scallops in clear water and quiet weather. The pole was 8 m long and the average haul was 50–60 specimens per day, though it could be much higher in shallower waters with excellent weather. Following rain storms the turbid water made this virtually impossible.

Initially only simple dredges (about 75 cm wide) were used for fishing scallops. They were towed by small sampans, whose prototypes were brought by members of an expedition led by N. N. Muraviev-Amursky, the first governor-general of the Ussuri Territory, together with boats from neighbouring countries. Their displacement was 1–1.5 t, and they used sails or one oar, the so-called “yula”. Industrial fishing by means of cords was unique at that time. It was performed in the following way: an anchored buoy was placed in the centre of the catching site and a cord was attached to it. The cord had length of 200 m and was 1–3 mm in diameter. The small lead loads (11–15 g each) were fixed to the cord at intervals of every 2 m. The catcher would sail in a boat to drag the cord and start making circles near the buoy. When the cord was trapped by the open scallop valves, the molluscs would abruptly close them and affix themselves. The more often the catcher would pull the cord, the tighter the bivalves would grip the gear. On even ground, a good catcher would haul several thousand scallops. In 1919–1920, Yesso scallop in Ussuri Territory was fished by professional women-divers with the ability to stay underwater for long periods of time even in the cold autumn months. At the end of 1920's when diving gear and motorboats equipped with dredges were introduced, greater scallop hauls were caught. When the Association for Exploiting Marine Resources was especially active the stocks rapidly diminished. After World War II industrial fishing was resumed for a short period of time but then totally banned in 1960.

Yesso scallops and commercial scallops (*C. albida*, *C. behringiana* and *C. chosonica*) were fished using small seiners (about 300 tons displacement) on the coasts of northern Primorye, southern Sakhalin, Kurile Islands and the Bering Sea. This involves a steel dredge, which is 1.5–3.0 m wide. The dredge is towed for 5–30 min. In Kuriles, one such haul would yield 0.39–1.28 tons of shells (Kochnev 1987). In Peter the Great Bay, divers use free diving down to 5 m and SCUBA diving down to 30 m to gather Yesso scallops.

24.4.1.3 Yesso scallop landings

Scallops are the most intensively consumed and fished bivalve molluscs. The best known is the Yesso scallop, *M. yessoensis*. For a long time these molluscs were an object of traditional catching (Tables 24.7 and 24.8).

24.4.1.3.1 Primorsky territory

Yesso scallop landings in southern Primorye were apparently not recorded for a long period of time. Starting in 1919, when diver boats were introduced, scallop hauls reached the impressive figure of 400 tons. By 1920, industrial fishing grew threefold, but in subsequent years, it sharply declined and then almost stopped. A Trust for Marine

Fisheries was organised in 1933 in Vladivostok with a network of enterprises all over the Soviet Far East. The new outfit resumed industrial fishing of the Yesso scallop to raise the average hauls for 1933–1937 up to 900 tons (Table 24.7). In subsequent years, the scallop was not fished and only 160 tons were landed in 1948–1949.

24.4.1.3.2 Sakhalin-Kurile region

In addition to the fishing areas in southern Primorye, the Yesso scallop was harvested in Sakhalin-Kurile areas. The commercial fishing of Yesso scallops at Sakhalin and Kurile Islands by Japanese fishers occurred from the 1930's to 1945. The main fishing area at that time was Aniva Bay. Between 1933 and 1943, annual yield was 1,000–2,300 tons. At Southern Kuriles values for landings were significantly greater (Skalkin 1966).

Commercial exploitation of scallop populations after World War II was founded by Russian fishers in 1961. The scallops were only fished with dredges from small seiners (Kochnev 1993). One year later in 1962 the catch of molluscs peaked at 5,230 tons. In the four following years, because of excessive catching, the annual yields in Aniva Bay decreased to only 30 tons (Table 24.8). Although it was a stable but poorly maintained population of scallops, the commercial stock of this population was evaluated at about 3,600 t. The reason for such a decrease was the dredging method of catching scallops and in 1967 catching of scallops in Aniva Bay was banned. In 2000, after a long prohibition, commercial catching using dredging was reinstated again in Aniva Bay (Shpakova 2001b).

Several years later commercial catching was banned at Southern Kuriles. At Terpenie Bay scallop landings endured for only one more year. As in Aniva Bay, annual yields were decreased because of excessive and irrational catching (Table 24.8). Between 1976 and 1984, commercial catching was reinstated and the annual yields were 9.5–282.9 tons. From 1985 to the present catching of scallops has been banned (Kochnev 1993) in Southern Kuriles.

24.4.1.4 Yesso scallop commercial stock

24.4.1.4.1 Primorsky territory

The commercial reserves of natural Yesso scallops along the coast of Primorye are presently exhausted after the last decade of irrational catching and poaching.

24.4.1.4.2 Sakhalin-Kurile region

Commercial populations of Yesso scallops along the coast of Sakhalin Island at Aniva and Terpenie Bays are shown on the map (Fig. 24.9). Commercial stocks at Tartar Strait have not been estimated.

Table 24.7

Annual catch (metric tons*) of Yesso scallop in Primorsky Territory in 1919–1937 (Belogradov 1981).

Years	1919	1920	1923–1926	1933–1937	1948–1949
Catch	400	1,200	35	900	160

* To remove the confusion originated with using out-of-date units in first edition (Kalashnikov 1991) we shall use metrical ones.

*Experimental fishing

24.4.1.4.2.1 Aniva Bay

In Aniva Bay, Yesso scallops are found along western and north eastern coasts at depths of 8–30 meters. Their distribution has an irregular and mosaic pattern. The total stock in Aniva Bay is estimated at 16,030 t (79.37 million scallops) with 4,970 t (15.63 million scallops) of them being of commercial stock (Shpakova 2001a). Settlement densities on bottom grounds in the bathymetric range of 7–21 meters average 4.33 specimens m⁻² with an average biomass up to 0.3 kg m⁻². Average shell height of the commercial molluscs (14–99%) is between 139–156 mm (Shpakova 2001a, b).

24.4.1.4.2.2 Terpenie Bay

In Terpenie Bay, Yesso scallops are distributed along the north eastern coast in waters 11–20 m deep. Total stock in Terpenie Bay is estimated at 1,300 tons (2.1 million scallops) but only 600 tons of them are of commercial stock. Settlement densities on bottom grounds average 0.03 specimens m⁻² with an average biomass of 0.008 kg m⁻². Average shell height of the commercial molluscs is about 167.1 ± 6.9 mm at individual biomass of 518.7 ± 9.8 g. Mean age of population is about 6.9 years.

24.4.1.4.2.3 Kuriles

In Kuriles, commercial assemblages of Yesso scallop are known in shallow waters of Kunashir Island and on the South Kuriles Shoal (Fig. 24.9). Total stock is specified as 40,000 t (200–300 million scallops) with about 18,000 tons of commercial stock (Ponurovsky et al. 2000; Ponurovsky and Brykov 2001). Settlement densities on bottom grounds in the bathymetric range of 5–20 m average 0.5 specimens m⁻². Average shell height of the commercial molluscs (44.8% of total population) is 126.8 ± 1.1 mm. Mean age of population is 3.5 years with the maximum lifetime of 12 yr.

24.4.1.5 Commercial Chlamys scallops

In addition to *M. yessoensis*, some scallops from the genus *Chlamys* have trade significance. These are less known because of their smaller size and their occurrence at depths greater than 50 m. The most abundant of them in north western Pacific are white scallops, *C. albida*, pink scallops, *C. chosenica*, and Bering Sea's scallops, *C. behringiana*. The Asiatic scallops, *C. asiatica*, rarely occur here.

24.4.1.5.1 Primorye

In Primorye, *Chlamys* scallops, mainly *C. chosenica*, form concentrations at depths between 25–250 m. Myasnikov (1982) reported three large populations of pink scallops along the northern coast of Primorye (stretching from Cape Povorotnyj to Cape Zolotoj). The highest density of settlements reaches up to 25 specimens m⁻² with an average of five specimens m⁻². Total stock of scallops is estimated at 420,000 tons (10.6 million scallops)

located at depths of 90–100 m. Since 1990 these reserves have provided annual yields of 1,000 t (Myasnikov and Hen 1990).

24.4.1.5.2 Kurile Islands

On the Kurile Islands, commercial fishing of *Chlamys* scallops by Japanese fishers occurred from the 1930's to World War II (Skalkin 1975). After 1972, there was a renewal of commercial fishing. From 1972 to 1975 annual yields did not exceed 140–1,170 t. After 1976 annual yields increased up to 1,500–3,050 t with an average of 1,990 tons. Major scallop landings (about 75% of annual yield) are derived from the Sea of Okhotsk side of Onekotan Island at depths between 50–200 m (Kochnev 1987). It is now the most stable scallop fishery in the Russian Far East region (Myasnikov et al. 1992). Two species (*C. albida* and *C. chosonica*) occur in mixed settlements. Due to an intense fishing increase the annual yields was 3,462–7,198 t with an average of 4,693 t (Table 24.9).

Populations of *Chlamys* scallops on Onekotan Island are found on both the Sea of Okhotsk side and at pacific side of the island. On the Sea of Okhotsk side of the island scallops are distributed over depths of 40–140 m. Density of settlements on the bottom grounds are 90.0 specimens m^{-2} with a biomass of 6.0 kg m^{-2} . Average density and average biomass are 2.7 specimens m^{-2} and 0.25 kg m^{-2} , respectfully. On the pacific side of the island, the largest density of scallops was found between 40–100 m. Densities of settlements on bottom grounds on this side are as high as 175 specimens m^{-2} . Total stock of *Chlamys* scallops in the region is estimated at 64,400 t (730.5 million scallops) with about 42,000 t of commercial stock.

Table 24.9

Annual catch (metric tons) of *Chlamys* scallops near Onekotan Island (Kurile Islands) in 1976–1997 (by Kochnev 1993).

Year	Catch	Year	Catch
1976	1,601	1987	2,700
1977	3,050	1988	2,000
1978	2,392	1989	2,898
1979	2,317	1990	1,754
1980	1,501	1991	1,494
1981	1,625	1992	2,400
1982	1,543	1993	3,462
1983	2,101	1994	7,198
1984	1,413	1995	3,574
1985	2,370	1996	4,963
1986	2,945	1997	4,269

24.4.1.5.3 In Bering Sea

In the Bering Sea commercial concentrations of Bering Sea's scallop *C. behringiana* are found (Myasnikov 1992). Commercial stock of scallops is estimated at 3,000 t within bathymetric range of 110–120 m.

24.4.1.6 Other *Chlamys* species

Along with the commercial importance of *Chlamys* species described above there are other potential species such as the Japanese scallop, *C. farreri*, and the Swift's scallop, *C. swifti*.

24.4.1.6.1 *Chlamys farreri*

The Japanese scallop, *C. farreri*, is the most thermophilic scallop in Russian waters. It only occurs in southern Primorye (Fig. 24.6). Afreichuk (1992b) reported concentrations in Posjet Bay. The total stock is estimated at several thousand tons located at depths between 3–5 m. Commercial stock has not been estimated. This species is an object for mariculture and fishery in East Asian countries (Wang and Shieh 1991). In Russia, mainly in southern Primorye, the Japanese scallop is one of most promising species for fishery and mariculture (Bregman 1982; Afreichuk 1992a).

24.4.1.6.2 *Chlamys swifti*

Stocks of Swift's scallop, *C. swifti*, in Primorye have not been evaluated. In Aniva Bay, Swift scallops are found between 2–19 m. Average density of settlements on bottom grounds ranges from 0.04 to 5.50 specimen m^{-2} with an average of 0.17 specimen m^{-2} . Biomass ranges from 3.8 to 498.8 g m^{-2} , with an average of less than 16 g m^{-2} . Shell height ranges between 32–114 mm with an average of 86.8 mm. Individual biomass ranges from 24 to 208 g with an average of 94.1 g. Although this species is widespread in the bay it does not form commercial aggregations because of its low density.

24.4.2 Aquaculture

The Yesso scallop, *M. yessoensis*, is the only scallop species cultured in Russia. It is cultured in the coastal waters of Primorye in the north western part of the Sea of Japan.

24.4.2.1 History

After the ban on scallop fishing in Primorye in 1962 stocks were replenished very slowly. The first steps in the mariculture of Yesso scallops in the Russian Far East occurred after 1968. In 1971, after several years of research, the first scallop farm was organised in Posjet Bay (southern Primorye). This industry reached its greatest development in Primorye in the 1980's. In addition to the farm in southern Primorye,

experimental work for spat collection was attempted in the 1970's in Sakhalin in Bousse lagoon but further cultivation was discontinued. Mariculture at this time had financial assistance from the largest fishing enterprises of region, such as "Dal'ryba" and "Primorrbprom" and from Ministry of Fishery of the USSR.

By the mid-1980's production reached over 10 million spat a year and at least 40 million one-year-olds were settled in various sites within Posjet Bay. Since 1977, in addition to its own plantations, the Posjet farm transferred 2–10 million young scallops from other bays to other marine farms. Starting in 1983, scallop cultivators in Posjet Bay collected 30 million spat, while industrial production was only 20–50 tons. It was not until 1989 that production output exceeded 100 t (Table 24.10).

In the 1990's, during the crash of the socialist system and the disintegration of the USSR, all the created farms were bankrupted or crisis-ridden. Since the end of the 1990's with the formation of the exchange relations in the Russian Federation, a new period in mariculture development has started. After the economic depression in 1997 the interest in mariculture has increased and a new period of economic expansion has started.

24.4.2.2 Present situation

The number of scallop farms in Primorye is quickly growing (Table 24.10). There are now 20 Yesso scallop farms with a total area of more than 700 hectares of single-crop area. There are 125 hectares of hanging culture and about 600 hectares under sowing culture. The development of mariculture in the Sakhalin region has been completely terminated.

Table 24.10

Twenty years (1981–2000) annual trend in number of organisations involved in Yesso scallop culture and total production (metric tons) in Primorsky Territory. Figures have been compiled from reports of fishery organisations.

Years	Number of farms	Yield	Years	Number of farms	Yield
1981	3	9.0	1991	5	153.0
1982	3	4.5	1992	5	150.0
1983	3	18.1	1993	5	155.0
1984	3	38.0	1994	5	110.0
1985	4	10.4	1995	6	113.0
1986	4	48.8	1996	8	22.0
1987	4	62.3	1997	9	60.0
1988	4	64.0	1998	10	131.0
1989	5	196.0	1999	18	99.6
1990	5	122.5	2000	20	91.2

24.4.2.3 Marketing

Almost all of scallop production from scallop farms is unprocessed. Unprocessed Yesso scallops are frozen as packed meats and a very small percentage of scallops (within 1%) are cooled in the shells. As for commercial scallops (*Chlamys* spp.), in most cases they are processed by canning. In Vladivostok fish stores and supermarkets, frozen meat may be sold for 280–340 rubles per kilogram (equivalent of \$9.3–11.3). Cooled whole scallops are sold for 20 rubles per shell (equivalent of \$0.7). For comparison, the cost of frozen beef is equivalent to \$2.5–3.0 (75–90 rubles) per kg. Canned scallops (in sauce, oil and smoked) are sold for the equivalent of \$2.0–4.0 (30–60 rubles) per 8 oz. In other Russian regions prices are a little bit higher. It is profitable to cultivate scallops at this price. In Vladivostok, several dozen tons are sold every year, which is highly insufficient even for the small local market. Frozen scallop meat is in high demand in spite of a high price. Yet, the scales of cultivation do not match the levels of need.

24.4.2.4 The culture methods

All the methods used in the cultivation of Yesso scallops can be assigned to one of two categories: off-bottom cultivation or on-bottom cultivation. Experiments were conducted to harvest spat in closed and running controlled systems involving artificial spawning and larvae feeding. This technique is not popular because it is too complicated and expensive. Attempts were also made to create commercial scallop concentrations by using artificial reefs. The results concluded that this was an inefficient process.

There are two main Japanese methods for commercial cultivation: hanging culture (cultivation of the scallop in cages) and sowing culture (cultivation on the bottom substrates of bays and inlets; Ventilla 1982).

24.4.2.4.1 Spat collection

Long-line structures with plates or bags as collectors are commonly used for spat collection in Primorye. Long-lines are a series of floats (Ø 240–300 mm) connected together by horizontal lines (Ø 19–22 mm) that supports a large number of vertical ropes with attached collectors. There are two types of collectors:

- 1 - Conical plates of perforated plastic (Ø 250 mm) covered by mesh stockings (7–12 mm). Twenty-five collector plates are strung onto the rope (Ø 6–8 mm) as garland up to 2.5 m long.
- 2 - Commercial onion bags with mesh or monofilament filling (capron or polyethylene). The bags are attached in sets of ten to the rope (Ø 6–8 mm) as garland up to 5 m long.

Prepared garlands of collectors are placed at depths between 5–10 m in semi-closed bays and inlets and at depths between 15–20 m in open waters. Mass scallop spawning in southern Primorye starts in mid-May. In order not to miss the settling peak, collectors are

hung deep in the water for 15–20 days in early June, so the substrates would be covered with a bacterial-algal film. This is used to promote spat attachment prior to larvae settling (Belogradov 1986). In southern Primorye settlement occurs in mid-June, 22–30 days after spawning begins. The size range of settling larvae is 250–275 μm . By the beginning of August, the spat average 3 mm in size and have growth rates of 3–4 mm per month.

There is a direct relationship between larval concentrations in the plankton and spat abundance found on the collectors. At larval concentrations in the range of 20–30 larvae m^{-3} spatfall is about 100–400 spat per collector and at 50–100 larvae m^{-3} it is up to 500–1,500 spat per collector. The long-term maximal larval concentration in plankton is 600 larvae m^{-3} (Belogradov 1981).

One month after settling spat size averages 10 mm. At least 200 spat have to settle in the collector in order for the result to be considered commercially profitable. In bonanza years 400–600, and even as many as 1,000 larvae can settle in a collector. In lean years, settling numbers from several to several dozen spat will make processing commercially unprofitable.

24.4.2.4.2 Intermediate culture

The long-line for intermediate culture is set up similar to that of spat collector lines. Horizontal lines support a large number of vertical garlands of cages.

In autumn, the collected spat (200–250 samples) are manually removed to hanging multi-tier cages (0.12 m^2). Spat are collected and directly placed in cages from a raft above the plantation. The collectors are lifted from the water to remove the substrate and spat are scraped off into vats filled with water. All foreign organisms (mostly mussels) and empty shells are removed during the transfer process. The necessary numbers of scallops are poured into cages and instantly placed back into the water. When performing this work, the scallop farmer will put a tent over the raft to protect the scallops from desiccation and the sun. In wintertime, the floating structures on which the cages are hung are placed under ice to protect them from destruction by moving ice floes. All structures are preferentially placed under the water to protect from heavy waves.

By April and May, scallops grown in these cages average 25–30 mm in height. When cultivation is performed correctly the survival rate is approximately 90%. Most mortality occurs at the beginning and is due to the stress of the transfer and to the fragility of the thin shell. The viability of these scallops is dozens of times higher than in the autumn, and several methods are used to subsequently cultivate them to marketable size. At 30 mm the juveniles can be sowed in open waters. About 70% are used for sowing culture and the rest are used for hanging culture in lower density cages.

24.4.2.4.3 Transport of scallop seed

When scallop seed are sold to other farms, or delivered for sowing on the bottom, they are packed up in boxes (volume 20–60 L) with perforated walls and bottoms. The boxes are put under the canvas on board a transport deck and should be instantly filled with molluscs in layers of 20–30 cm. Scallop seed should be covered with moist algae or

seaweed leaves after being taken out of the water. During transportation, the boxes are replenished by outboard water every 30 minutes. Transportation is preferable when the water and air temperatures are approximately the same (about 5–10°C). In this manner, the scallops can survive for 24 hours (Table 24.11).

24.4.2.4.4 Sowing or on-bottom culture

Sowing cultivation is based on the principle of transferring scallop juveniles from areas where they settled in great abundance, to bottom grounds, where they can be spread at lower density in order to obtain better growth rates and weights. Sowing culture is practised more widely in Primorye.

Scallops are usually transferred after intermediate culture to bottom grounds in May and June when they are about one year old. Specific sites should be pre-selected before the sowing on sandy-silty sediments or on shingle-shell mixtures and should be without starfish (or at most 0.5 specimens m⁻²). The content of finely dispersed silt (particles smaller than 130 µm) shall not exceed 30%. Bottom grounds shall be at least 3 m deep in inlets protected from wave action. They should be over 10 m deep in open waters, partially protected from prevailing winds and over 20 m deep at bays opened to all winds, so that storms will not ruin the benthic habitat. Areas with natural scallop accumulations (past or present) are preferable for sowing culture. The selected sites should be established by taking bearings on shore to reference marks and then mapped. Prior to sowing the water space should be marked with buoys. The vessel should sail between the buoys at low speeds, and the one-year-old scallops will be evenly scattered all along the bottom grounds with a density of 10–20 specimens m⁻². Sowed scallops usually weigh less and are 10–15 mm smaller in shell height than native scallops (Silina 1994). This difference usually continues throughout the lifetime of scallops. It is thought that the slower growth of sowed scallops from collectors or cages unfavourably affects the growth during winter and spring when the densities are high. Additionally, some of the growth inhibition results from shell breakage during transportation and sowing on the bottom. Growth of sowed scallops is further reduced while the animals adapt to their new habitat and generate new shell at the ventral margins. Depending on the temperature and other ground conditions, the scallops will grow to marketable sizes in two to four years. Survival on the sea floor will depend on predation and wave intensity and may vary from 5 to 20% within the same grounds during different cultivation cycles.

In two to four years after sowing, SCUBA divers collect marketable scallops. Their productivity on shallow grounds (3–5 m deep) with densities over 10 samples m⁻² amounts to 1,500–3,000 scallops hr⁻¹. In cases of lower densities or larger depths and in turbid waters divers' productivity will progressively decline down to only 300 scallops hr⁻¹.

24.4.2.4.5 Hanging or off-bottom culture

Hanging cultivation adds a third dimension to the essentially two-dimensional sowing culture. The crop is spread over and can utilise a much greater proportion of the water column. The long-line for intermediate culture is set up in the same manner as that for the

Table 24.11

Survival rates (%) of Yesso scallops juveniles during transportation depending on temperature (Bregman 1987).

Duration of transportation, h	Temperature °C			
	5	10	15	20
3	98	98	95	90
5	97	96	93	88
10	95	94	91	85
15	93	92	85	80
20	92	91	83	75
25	90	88	80	70

intermediate culture. They are usually set deep (5–15 m from the surface) to escape wave action and the thermocline in the summer months. There are two schemes for hanging culture:

Young scallops with shell heights of 10–15 mm are placed into cages of 200–250 specimens. One-year old scallops (20–30 mm) are transferred into cages of 20–25 individuals and two-year-olds (50–70 mm) scallops of 5–7 individuals. In three years the scallops will reach the marketable size of 100 mm in height.

Young scallops with shell heights of 10–15 mm are placed into cages of 20–30 individuals and in 1.5 years are transferred to cages of 5–7 specimens. The number of transfers in the second case is smaller, but there is strong fouling on cages due to the longer period of time between operations. Fouling has a negative effect on scallop growth and survival.

All scallop transfer operations are performed in the spring and autumn at relatively low temperatures (about 10°C). When the work is performed correctly, survival rates average 90%. Most mortality occurs at the beginning since it is due to the stress of the transfer and to the fragility of the thin shell.

Harvesting methods require lifting of cages and collecting the scallops of marketable size. Manual harvesting is time-consuming and labour intensive. It is assisted by mechanical winches for lifting lines.

24.4.2.4.6 Obstacles to mariculture development

There are several obstacles to the development of mariculture in Russia:

- Financial problems of protracted payback periods in mariculture and the necessity of a huge investment in equipment. Lump-sum investments for the creation of mariculture farms exceed \$200,000. It is often very difficult to find investors for such a long-term project.
- Ethnic and gastronomic problems because shellfish are not a traditional nourishment of the Russian people.

- Legal problems arise from the absence of the laws regulating sea farming.
- Socio-economic problems concerned with undeveloped infrastructure of inshore population centres.

24.4.2.4.7 Ecological constraints associated with cultivation

24.4.2.4.7.1 Predation

As mentioned earlier, young scallops are often preyed upon by various starfish species. In mariculture, when their bipinnaria larvae reach concentrations of 20 specimens m^{-3} in plankton or when inside collectors they develop twice as fast as the scallop spat they may cause 100% mortality (Belogradov 1981; Gabaev 1981). During settling starfish larvae attach to the same collectors as the scallop juveniles. The average abundance of starfishes and scallops on spat collectors is shown in table 24.12. The relationship between the abundance dynamics of scallops and starfishes can be described by following equation (Gabaev 1990b):

$$A_{\text{scallops}} = 128.7 + 39.4 \cdot A_{\text{starfishes}} \quad (r = 0.82; p < 0.05), \quad (2)$$

Where A_{scallops} is the abundance of scallops (specimens m^{-2}) and $A_{\text{starfishes}}$ is the abundance of starfishes (specimens m^{-2}).

The relationship between the number of attached scallop juveniles and number of scallops consumed by starfish can be described by the following equation (Gabaev 1990b):

$$N_{\text{eating}} = 175.0 + 2.3 \cdot A_{\text{scallops}} \quad (r = 0.74; p < 0.05), \quad (3)$$

Where N_{eating} is the amount of eaten scallops (specimens) and A_{scallops} is the abundance of scallops on spat collectors (specimens m^{-2}). In other words the larger the abundance of scallop juveniles, the faster it decreases.

The gastropod *Nucella heyseana* is also a predator of scallops, which can cause similar problems (Gabaev and Kolotukhina 1999).

24.4.2.4.7.2 Epibionts

Farmed scallops constitute an excellent substrate for the settlement of many epifaunal and epifloral organisms. Almost 60 species of algae and invertebrates were noted on the shells of cultured scallops. In hanging culture, scallops are most frequently inhabited by other bivalve molluscs and barnacles (Silina and Ovsyannikova 2000). The dominant epibiotic species are mussels *Mytilus trossulus* (abundances up to 110 individuals per shell and biomass estimates of up to 46 g shell $^{-1}$), *Modiolus kurilensis* (up to 32 specimens) and *Hiattella arctica* (up to 27 specimens). Subdominants of epibiotic communities include barnacles, *Balanus improvisus* (up to 268 specimens per shell), *B. crenatus* (up to 189

Table 24.12

Average abundance (mean $\pm$ s.d.; specimens m^{-2}) of starfish and scallop juveniles on spat collectors at a scallop farm in Posjet Bay, Sea of Japan (Gabaev 1990).

1979	327 $\pm$ 89	2 $\pm$ 1	2 $\pm$ 1	2.0 $\pm$ 0.3
1980	22 $\pm$ 0.4	103 $\pm$ 25	3 $\pm$ 1	0.2 $\pm$ 0.1
1981	259 $\pm$ 56	84 $\pm$ 43	16 $\pm$ 9	1.1 $\pm$ 0.6
1982	160 $\pm$ 18	229 $\pm$ 65	1	0.1 $\pm$ 0.0
1983	1,060 $\pm$ 232	16 $\pm$ 11	29 $\pm$ 5	0.8 $\pm$ 0.1
1984	193 $\pm$ 16	66 $\pm$ 40	9 $\pm$ 7	0.0
1985	109 $\pm$ 1	74 $\pm$ 62	5 $\pm$ 2	0.0
1986	541 $\pm$ 337	0	5 $\pm$ 3	0.2 $\pm$ 0.1
1987	176 $\pm$ 36	1 $\pm$ 0.5	0.3	0.1 $\pm$ 0.05
1988	458 $\pm$ 165	0	0.4	0.02

specimens) and *Hesperibalanus hisperius* (up to 27 specimens). Scallops from wild populations have epibionts only on the upper valve. But in cultured scallops the fouling is presented on both valves and in cage culture epibionts are more abundant on the lower valve than on the upper valve. Because of cage overcrowding and immobility, epibionts in hanging culture are more extensive than in sowing culture.

In sowing culture, epibionts on scallop shells are mainly the barnacle *H. hisperius*. Their abundance can reach up to 77 specimens per a shell on two-year scallops and up to 337 specimens on three-year scallops (Silina et al. 2000; Silina and Ovsyannikova 2000).

Excessive fouling is a scallop-farming problem mainly by virtue of the extra effort required to clean the crop for marketing. It may also have some influence on growth rate and productivity through competition for space and reduction of water circulation. Again, farm management provides the best means of alleviating this problem, i.e., using optimal techniques for cultivation tending to sustain less fouling.

24.4.2.4.7.3 Biofouling of cultivation structures

According to the techniques of hanging culture existing in Russia, the cages are placed at depths of 5–15 m. These depths teem with the larvae of various organisms, many of which may form abundant fouling communities on all the parts of the structures. Maslennikov and Kashin (1993) reported strong fouling occurs on cages during cultivation. The fouling biomass reached 5.7 kg m^{-2} at a depth of 5–7 m. The dominant

species, accounting for more than 84% of the total biomass, is *M. trossulus* (4.9 kg m⁻² at a population density of over 10,000 specimens m⁻²). The fouling biomass on collectors at this depth horizon was 6.5 kg m⁻², of which *M. trossulus* and *B. improvisus* contributed 61.2 and 36.4%, respectively.

Fouling causes the weight of the structures to sharply increase and their storm resistance to decrease. This reduces the life span of these structures (Bregman and Kalashnikov 1983). When strong, fouling may also make the collectors and cages an inhospitable environment by restricting water flow through the bags, depleting nutrients, and hindering the growth of scallops within the collectors and cages. The rate of growth of the scallops (height and mass) is also strongly affected by fouling organisms.

Many ways of removing fouling organisms on sea farms (mechanical, physical, chemical and biological) are now known. Chemical methods are not suitable for scallop cultivation because they use toxic substances. The application of physical and mechanical methods is considerably limited because they damage cultivated molluscs or are very labour consuming.

24.4.2.4.8 Effect of scallop mariculture on coastal ecosystems

This section considers the effects of plantations for the cultivation of bivalve molluscs on the hydrological and chemical conditions of the marine environment and on the communities of marine organisms in coastal, semi-closed bays of the Russia seas. Due to eutrophication (from rearing molluscs in suspended culture), the species composition, structural and functional parameters of pelagic and benthic communities have changed. The rate of eutrophication depends on the configuration of the bays, intensity of the water exchange and the turbulence of bottom layer of water. After liquidation of mariculture facilities the biological components of ecosystems of semi-closed bays were restored within 5–10 yr.

The main scallop species cultivated in the Russian seas is the Yesso scallop, *Mizuhopecten yessoensis*. Molluscs are farmed in monoculture mostly in semi-closed bays. The common trend of rearing technologies for molluscs is the use of mariculture installations constructed of numerous ropes, supporting floats and suspended elements. The maintenance of these structures demands a great deal of manual work. For this reason, farming molluscs is often carrying out in areas protected from wind and storms. These technologies have a series of essential drawbacks which affect productivity and result in the high costs of production. In addition, mariculture structures become part of the environment. They become a substrate for the formation of settlements of many other organisms (fouling communities), change water exchange and hydrochemical conditions in bays, and affect the composition and structure of pelagic and bottom communities in adjacent water areas.

The fouling of the structures of a mariculture installations is one of most vivid examples of the interactions between mariculture facilities and the environment. Heavy fouling increases their gross weight and reduces their sustainability to storm action (Bregman and Kalashnikov 1983; Kotlovskaya 1984; Stotsenko 1984, Kashin and Maslennikov 1993). A population of fouling organisms is a large source of a great

number of larvae, settling on collectors, cages and other anthropogenic substrata. Fouling animals rival cultivated molluscs for the area, nutrition, oxygen and significantly affect production. Additionally, the fouling organisms aggravate the problems of fecal pollution due to the feces and pseudofeces of invertebrates (both fouling and cultivated). Organic matter accumulates on the bottom underneath plantations and stimulates aerobic and anaerobic bacterial decomposition.

Research assessing the effect of mariculture on coastal ecosystems is mixed. Influence of plantations was considered positive (Golikov and Scarlato 1979; Pereladov and Sergeeva 1989; Pogrebov et al. 1990) and negative (Levin 1981; Kucheryavenko 1986a; Zolotarev and Gubanov 1989; Gabaev 1990a; Kucheryavenko and Bregman 1995). An augmentation of the total biomass of macrobenthos (Golikov and Scarlato 1979; Golikov et al. 1986; Pogrebov et al. 1990) and of meiobenthos (Gal'tsova and Pavlyuk 1987), an increase in species diversity of the benthic population and the abundant growth of some hydrobionts in the areas of mariculture facilities (Pereladov and Sergeeva 1989; Pogrebov et al. 1990) are considered as arguments for a positive effect. Accumulation of biodeposits under plantations (Levin 1981; Zolotnitsky 1988; Sedova and Koshkareva 1989), changes in the biochemical composition of water (Kucheryavenko 1986a, b; Kucheryavenko and Bregman 1995), disruption of interspecific relations within communities (Gabaev 1990a), development of epizootic loci (Zolotarev and Gubanov 1989), and the decrease in the intensity of water exchange (Grigoryeva et al. 1996; Kucheryavenko and Bregman 1995) are referred to as negative effects. Bottom deposits directly under plantations may become completely lifeless within one and a half to two years or a burst of reproduction of an opportunist species followed by a vanishing of unsustainable species to organic pollution occurs during mariculture operations. Accumulation of rich organic bottom sediments and concomitant physical and chemical changes of substrate invoke deterioration of water quality and result in a sharp fall in the productivity of the mariculture facilities. The microbial decomposition of bottom organic matter occurs in the season of highest water temperatures which often causes oxygen deficiency. In places of artificial rearing of molluscs, the biochemical composition of the dissolved organic matter (DOM) differs from that in habitats of natural populations. This so-called "biological pollution" is observed in the areas of plantations (Levin 1981; Agatova et al. 1983; Development 1989; Sadykhova 1995).

The greatest number of publications concerning the Russian part of the Sea of Japan was devoted to functioning of mariculture plantations located in South Primorye in Posjet Bay and Alekseeva Bight (Popov Island) of the Peter the Great Bay (Fig. 24.15). Farming of the Yesso scallop, *Mizuhopecten yessoensis*, and of the Pacific mussel, *Mytilus trossulus*, in shallow and semi-closed bays of the Posjet Bay (Minonosok Inlet and Reid Pallada Bay) was implemented in the early 1970's. The total area of facilities for spat collecting and cultivating of molluscs was about 16 ha in Minonosok Bay and about 10 ha in Reid Pallada Bay.

Minonosok Bay is a semi-closed basin. It has an area of about 11 km² characterised by low water exchange. Its hydrological regime is regulated by tidal flows and no more than 10% of its water is exchanged per day (Kucheryavenko 1986b). The average speed of currents in the bay, due to installations for rearing of molluscs, has decreased from

6.9 cm s⁻¹ in the mouth to 3.8 cm s⁻¹ in the central part. At the innermost part of the bay the current speed is only 2.6 cm s⁻¹. The direction of the currents at various depths differs by up to tens degrees and becomes inverse under the influence of some of the elements of structures (Kucheryavenko and Bregman 1995). Nutrition requirements of farmed molluscs require about 56% of the potential trophic base of the bay (Sedova and Kucheryavenko 1995). In the same study it was recorded that molluscs filtered 5.5% of the total volume of water of the bay per day. Significant differences in DOM composition excreted by organisms at plantations and beyond were recorded (Agatova et al. 1983). It was revealed that cultivated molluscs significantly affect the biochemical composition of the water especially in close vicinity of the installations. By autumn the content of organic carbon was almost 2 times higher in Minonosok Bay due to the spawning of molluscs (May - August) (Kucheryavenko and Bregman 1995).

Figure 24.15. Map of sites mentioned in the text.

On surfaces of 1 m² located under the water column (volume of 2.5 m³) there are about 450 scallops existing by the technology of rearing (Sedova and Kucheryavenko 1995). The molluscs filter that volume of water in 2 h. The content of suspended organic matter (SOM) is reduced with water motion from one collector string to another but the concentration of dissolved metabolites is increased. Installations reduce water exchange in the bay by decreasing the speed of the tidal currents. These combined effects slow the growth rates of cultivated scallops in the direction from the mouth to the innermost parts of the bay (Sedova and Kucheryavenko 1995). With a large number of farmed molluscs silting of the bays is promoted by the accumulation of biodeposits.

The effect of the biodeposits on the ecosystem of the bay has been discussed in series of works (Agatova et al. 1983; Kucheryavenko and Rakov 1983; Kucheryavenko 1986a, b, 1988, 1989; Rakov 1986). It has been shown that significant amount of feces and pseudo-feces are discharged from plantations. However, there are no unambiguous answers concerning the effects of this process on the ecosystem (Kucheryavenko 1986b). Abundance of the fecal material dropping to the bottom may cause the development of anaerobic zones in the bottom sediments and the formation of hydrogen sulfide. Calculations show that cultivated molluscs excrete 10–15 tons of biodeposits per month. The actual amount of biodeposits may be even higher due to the additional feces of the fouling animals (Sedova and Kucheryavenko 1995). The maximum amount of biodeposits is discharged from plantations into adjacent environments during August and September and the minimum during the winter months (Kucheryavenko and Rakov 1983). Another study of Kucheryavenko (1988) describes the absence of a layer of biodeposits underneath plantations in Minonosok Inlet. This was attributed to high enzyme activity of the discharged suspension that resulted in its relatively quick decomposition. Gabaev (1990), summarising the operation of mariculture farm in Minonosok Inlet, drew conclusions on the degradation of benthic communities in the bay. Our examination of bottom (in 2000) confirmed the presence of a one-meter layer of silt deposits under mariculture plantations in the Minonosok Inlet.

In the semi-closed Alekseeva Bight (Popov Island) with the total area of 9 km², the rearing of Yesso scallops and mussels was conducted from 1978 to 1988. The mariculture farm in the Alekseeva Bight was liquidated in 1989. The area of suspended cultures varied from 2 to 6 ha during various years. The plantation reached its maximum area in 1986–87 of 14 ha. In addition to the scallop facilities there were also 500 collectors (about 3 ha) for mussel cultivating (Gal'tsova and Pavlyuk 1987).

Many authors have investigated the various aspects of the interactions of plantations and bay ecosystems. According to these assessments, molluscs from the Alekseeva Bight plantation discharged 17 t of biodeposits per year. They filtered 17% of the total volume of water per day and their nutrition requirement was 18% of all suspended organic matter of the bay (Sedova and Koshkareva 1989; Sedova and Kucheryavenko 1995). Growth rates of molluscs (*Mytilus trossulus*) were almost twice as high at the installations compared to their bottom-inhabiting vicariates (Soldatova et al. 1985).

Heavy silting of bottom and the depression and destruction of benthic communities was reported during the period of exploitation of the bay. Near the plantation there were changes in the microbial community. The number of benthic bacteria increased 5–10

times compared with that in a control area (Shcheglova and Bregman 1988). Meiobenthic researches have shown that there was a depletion of taxonomic structure and abnormal increases in populations of animals such as nematodes, harpacticids, and ostracods under the plantation (Gal'tsova and Pavlyuk 1987). The species composition of foraminiferans was also depleted under installations with the population density one order of magnitude lower than at areas away from installations (Tarasova and Preobrazhenskaya 2000).

Histopathological changes in gonads and disturbances of the development of progeny were recorded in sea urchins from the Alekseeva Bight (Vashchenko et al. 1992). An increase of heavy metal content in soft tissues of molluscs sampled from cages was observed (Chernova et al. 1988). Ichthyofauna of the bay has also changed. The fish species that are sensitive to the oxygen content of the water and to its overall quality have disappeared and the number of eurybiontic forms has increased (Gomelyuk et al. 1990). An increase in the abundance of the diatom, *Skeletonema costatum*, which is the indicator of eutrophication of a water basin, was observed during plankton research (Pautova 1987). In 1980 and 1982 there was a decrease of larval abundance of Yesso scallop and poor spat settling (Guida 1983). A trend of annual decreases in the number of trepang (*Apostichopus japonicus*) larvae was also recorded (Development 1984). Thus, in 1984 the number of trepang larvae was the lowest, compared to previous years. Only larvae of early developmental stages were observed in the plankton (Mokretsova and Gavriloza 1986). Significant decreases in the abundance and biodiversity of larval plankton were recorded in the meroplankton of the bay, compared to the mid 1970's (Korn and Kashin 1989). During its operation, the mollusc plantation rendered strong negative effects on the ecosystem of the bay (Pautova 1987).

Comparing data collected from 1986–1990 (Maslennikov et al. 1994) with data from 1973–74 (Mikulich and Biryulina 1977) reveals a sharp reduction in the abundance of larvae of common groups of invertebrates during the period of the maximum operations at the mariculture facilities in the Alekseeva Bight. The total number in the summer season decreased from several thousands of individuals down to only 500–800 individuals per m^3 . In September of 1986, the maximal density of bivalve larvae was 785 individuals m^{-3} (Mikulich and Biryulina 1977). It had reached 5,260 individuals m^{-3} prior to installation of mariculture facilities (1973–74). In October of 1987, the number of polychaete larvae recorded was about 200 individuals m^{-3} . The average density in 1973–74 was 6,300 individuals m^{-3} with a maximum density of 22,760 individuals m^{-3} . In April of 1987, the maximum density of decapod larvae was only 20 individuals m^{-3} . Prior to the operations at the mariculture farm, the number of shrimp larvae was 170 individuals m^{-3} and that of crabs was 68 individuals m^{-3} . Only the number of gastropod larvae has comparable values with the previous data. The greatest changes took place for echinoderm larvae. In 1986–88 the brittle star, starfish and trepang larvae did not occur but individual sea urchin larvae were recorded. According to 1973–74 data the maximum total number of echinoderms reached 5,500 individuals m^{-3} . In 1974, of the 1,700 individuals m^{-3} only brittle star larvae were recorded in May and in September their density exceeded 400 individuals m^{-3} .

The effect of pollution on larvae may be mediated through the disturbances of the development of sex cells in mature animals giving rise to nonviable progeny of single

Figure 24.16. Multi-year variations in overall number of larval plankton in Alekseev Inlet in 1973–1974 (Mikulich, Biryulina 1977) and in 1986–1990 (our data). Date; month, year. Larval density; individuals per m³.

The use of natural biotopes for artificial farming should not result in exhaustion of bioproduction potential. Cultivating of mass of molluscs is based on the use of this potential. Thus, artificially high densities of hydrobionts of one or several species, not intrinsic to the natural biotope, are created in a small area. Such modified communities should be balanced by the preservation of bioproduction potential, i.e., all the effects of industrial population of hydrobionts (seaweed, molluscs, fishes, etc.) on environment should not fall outside the limits of those "reparations" which are capable of providing the natural community. The community of organisms as a balanced system may only exist under conditions when products of metabolism of its incorporated populations do not accumulate in the biotope and do not vary in parameters corresponding to the structural and functional traits of community. Pollution results in a decrease in the total number of invertebrates, a decrease of indexes of species diversity and of total number of taxa in community. Thus, at places for the cultivation of molluscs there are all the prerequisites for the destruction of the bottom ecosystems eventually leading to the general decrease of output of production of mariculture (Gabaev 1990a).

Elements and structures of facilities that are in the water column significantly decrease water exchange at plantations (Babkov 1989; Kulakovsky and Sukhotin 1989; Silkin and Khailov 1988). The amount of nutrients coming into the mariculture farm, the growth rate of molluscs at the installations, the biomass of fouling communities, and the removal of metabolites all depend on the magnitude of this water exchange (Khalaman and Kulakovsky 1989; Khalaman and Sukhotin 1989). Reared molluscs and fouling species transform almost all seston into bottom sediments (except for organic material used for their feeding). Thus, bays with facilities for mollusc farming are traps for seston. Eutrophication results from the decrease in water exchange by exceeding inputs of biogenic elements and of organic matter from the plantations. It is further aggravated by high mortalities during seasons of the highest water temperatures and formation of bottom hypoxia. The sedimentation of seston and the low oxygen concentrations result in the degradation of benthic communities. On the other hand, excretions from molluscs may enhance the development of phytoplankton. At high concentrations, the relatively large phytoplankton cells sediment to the bottom in the form of pseudofeces. The rate of consumption at plantations (in water column) is higher than at natural substrates (Mikulich 1986). Nutritional requirements of molluscs farmed in bays vary from 20% to 59% of the trophic potential of the water basin (Alimov 1989; Sedova and Koshkareva 1989). As a result of using existing technologies for cultivating molluscs in semi-closed bays with low water exchange, silting of the bottom and biogenic pollution of the water area occur. This results in the depression of the development of one of the organisms and the enhanced reproduction of the other (opportunistic species) which disrupts the dynamic equilibrium of the ecosystem.

The generalised pattern of the interactions between the mariculture facilities and the natural ecosystem is shown in figure 24.17. Mollusc plantations in the waters of shallow bays may result in the following effects:

- Changes in the hydrological regime and decreases of water exchange;
- Changes in the specific communities of fouling organisms and farmed molluscs on mariculture facilities in water column;

- Cultivated molluscs and fouling organisms from mariculture installations filter a significant volume of water of a bay, thus their nutrition requirements consume a great part of the trophic potential of bays which mariculture facilities are located;
- Changes in the biochemical composition of the adjacent water areas due to the effects of exometabolites discharged from the plantation;
- The structure and dynamics of phyto- and zooplankton changes, species diversity and number of larvae of benthic invertebrate decreases;
- Settling of juveniles of commercial invertebrates (spat) on collectors decreases;
- Biodeposits from plantations cause silting of ground sediments;
- Number of heterotrophic microorganisms increases under plantations;
- At plantation areas a decrease in species diversity of macro- and meiofauna including changes in benthic communities;
- Changes of biota many times exceeding the size of plantations themselves.

To mitigate these potential effects technology of scallop rearing in open water areas has been developed at the Institute of Marine Biology of Far East Branch of Russian Academy of Sciences. These areas are less affected and at the same time have sufficient space to avoid competition with traditional species. That technology provides joint farming of Yesso scallop, *Mizuhopecten yessoensis*, and Red King crab, *Paralitodes camtschaticus*, in polyculture (Maslennikov 1998; Maslennikov and Kashin 1998). Thus, not only is the commercial cultivation of scallops and Japanese kelp achieved, the operations are also restoring the wild populations of Red King crab in the Far East seas (Maslennikov 1999).

24.4.2.5 Future prospects

The future of Yesso scallop farming is very promising. The market is constantly growing as demand continues to exceed supply. There is some potential for increased farming. Production of scallop farms might be increased through better scallop farm management and the application of technological innovations for mariculture.

There are prerequisites for future mariculture development in Primorye and the northern part of the Russian Far East including historical, organisational, market opportunities, resource environment and socio-economic (Arzamastsev 2000). According to experts, the inshore waters suitable for development of maricultural farms includes approximately 6,000–10,000 hectares in Primorye alone. This provides commercial output of 700,000 tons (Mokretsova 1996). In coastal waters of the Sakhalin and Kurile Islands, natural resources and environmental conditions are also favourable. The optimum place for mariculture development was found in shoaling waters of southern Sakhalin (Kochnev 2000) and South Kurile Shoal (Ponurovsky et al. 2000).

One of the promising trends of mariculture is polyculture. Scallop populations that spontaneously developed under kelp plantations at kelp farms, are well known in practice (Shal'dybin 1983). Moreover, joint cultivation of kelps and scallops will help protect against excessive eutrophication, which often occurs at mollusc and kelp farms from overcrowding (Arakawa et al. 1971; Ventilla 1982; Rosenthal et al. 1988; Ivin 1999).

Figure 24.17. A schematic of scallop farming impact on coastal ecosystem.

Not long ago a project on the joint cultivation of Yesso scallops *M. yessoensis*, Japanese kelp *Laminaria japonica* and common sea cucumbers *Apostichopus japonicus* was conducted (Ivin and Maslennikov 2000; 2001). This project started in 2000 by one of the biggest joint stock companies of aquaculture and recently about 100 million spat were collected and more than 40 million scallop seed and 30,000 juvenile sea cucumbers were sowed. The methods for cultivation and construction of structures applied in the project were originally developed and protected by a patent of the Russian Federation No. 2149541 (Maslennikov and Kashin 2000). One hectare of sea farms can yield up to 400,000 market-sized scallops. This is equal to 8 tons of scallop meat. Kelp productivity is not less than 50 ton in wet weight or about 10 tons in dry weight. Technology of sea cucumber cultivation can yield up to 10,000 market-sized individuals. The projected profitability of the sea farms is about 15–18%.

World experiences with mariculture are driving sea farms transferred from closed bays to open waters. The technology uses open seawaters with depths of more than 30 m which are unsuitable for traditional mariculture. The shallow bays with depths of 10–15 m are used only during a short period (not longer than 6 months) for the collection of scallop spat and sea cucumber juveniles. Areas which are occupied by maricultural structures will cover no more than 33% of the general area for sea farms. The remaining water space is used as a reserve for the rotation of areas occupied by the cultivation of sea organisms. After termination of each culture cycle, the plantations will be relocated to a new area. This allows areas that are used in mariculture to be maintained in a natural state. Turnover of used areas allows long-term usage of sea farms without negative environmental impact. This rotational scheme has long been applied in agriculture.

Chapter 25

Scallop Aquaculture and Fisheries in Brazil

Guilherme S. Rupp and G. Jay Parsons

25.1 INTRODUCTION

The Brazilian coast extends for more than 8,000 km along the Western Atlantic Ocean and ranges latitudinally from about 5° N to 33° S, being the largest tropical and subtropical coastline in the world (Fig. 25.1). Approximately 45% of the Brazilian population live within 200 km of the coast, which corresponded to approximately 70 million inhabitants in 1999 (Anonymous 1999). Although there are several well-preserved areas, anthropological pressure is causing serious environmental impacts on the coastal zone, such as marine pollution and damage to mangroves, estuaries, and other important ecosystems (Ab'Sáber 2001). The degradation of these nursery grounds of fishery resources along with overfishing and mismanagement by public agencies, are contributing to a decline of artisanal fishery production, which is an important socio-economic activity in several states. Recently, bivalve aquaculture has started to emerge as an important economic alternative to the declining artisanal fisheries in different areas of Brazil. As a result, the demand for unpolluted waters for bivalve growth is contributing to increased environmental awareness in coastal communities, as well as eliciting public action towards improvement of seawater quality and proper coastal zone management. Furthermore, along the Brazilian coast there are vast marine areas with pristine waters potentially available for future development of bivalve aquaculture, including scallops.

The Pectinidae is represented in Brazilian waters by 6 genera and 16 species (Rios 1994). Among them, two species are notable for their economic interest: the lion's paw scallop (Fig. 25.2), *Nodipecten* (= *Lyropecten*) *nodosus* (Linnaeus, 1758) and the zigzag scallop *Euvola* (= *Pecten*) *ziczac* (Linnaeus, 1758). *N. nodosus* is locally known as "vieira", "pata-de-leão" or in some areas "coquille", as a gallic derivation from a European scallop. *E. ziczac* is locally known as "vieira". The former is the largest scallop occurring in Brazilian tropical and subtropical waters, and has recently been the focus of increasing interest for aquaculture development (Rupp 1994, 1997, 2001, Uriarte et al. 2001). The latter has previously been the subject of a significant fishery, but stocks have recently declined and landings have dwindled. *Aequipecten* (= *Chlamys*) *tehuatlchus* (Orbigny, 1846) is another species having potential economic interest in Brazil. Although it is an important fishery resource in Argentina and has aquaculture potential (Narvarte 1995), the absence of commercially significant stocks in Brazil precludes, at this time, any economic utilisation of *A. tehuatlchus*. Other edible scallops from waters off south Brazil are *Chlamys felipponei* (Dall, 1922) and *Chlamys patagonicus* (King, 1832) (Rios 1994), which reaches about 7 cm in shell height, but no economically valuable stocks are known

Figure 25.1. Map showing location of Brazil in the Americas, and in detail the States of Santa Catarina (SC), Paraná (PR), São Paulo, (SP) and Rio de Janeiro (RJ), where there are activities of scallop fishery and aquaculture.

Figure 25.2. Left (superior) valve of *Nodipecten nodosus* (Linnaeus, 1758). Scale: shell length = 145 mm.

in the area. The remaining species, due to small sizes, have no potential for aquaculture or fisheries.

The next section of this review focuses on aspects of the biology and aquaculture of *Nodipecten nodosus*. As well, a small recreational fishery based upon this species will be described. In the last section, the information available on the biology, aquaculture and fishery of *Euvola ziczac* are discussed.

25.2 *Nodipecten nodosus* – BIOLOGY, AQUACULTURE AND FISHERIES

25.2.1 Taxonomy and Distribution

As an historic remark, the first record for *Nodipecten nodosus* in Brazilian waters was made by Haas (1953) who reported that *Pecten (Nodipecten) nodosus* Linnaeus, was collected by the Brazilian naturalist Helmut Sick off Ilha Grande, Rio de Janeiro (RJ), “almost under the Tropic of Capricorn” and sent to the Chicago Natural History Museum.

In recent literature, certain controversy persists with regard to the taxonomy of the genera *Nodipecten* and *Lyropecten*. Smith (1991) presents the distinction between both genera and characterises the different species. *Lyropecten* is an extinct genus in the Atlantic Ocean, and the only living species is *L. magnificus*, found in the Pacific Ocean off the Galapagos Islands. *Nodipecten* has extant representatives in the Atlantic and Pacific. In the Western Atlantic two holocene species of *Nodipecten* are found, *N. fragosus*, which inhabits warm-temperate waters from the Gulf of Mexico to Cape Hatteras (North Carolina) in depths from 15 to 82 m, and *N. nodosus*, which is found from the Caribbean southwards. In the Pacific Ocean, *N. subnodosus* occurs off the west coast of Mexico and Baja California and *N. arthriticus* occurs from Mexico to northern Peru. According to Smith (1991), *N. nodosus* is the ancestor of *N. subnodosus*, but they no longer live adjacent to each other, speciation having occurred after the closure of the Panama Isthmus. The presence of bulbous hollow nodes is a distinctive characteristic of the genus *Nodipecten*. Taxonomic distinction between *N. nodosus* and *N. fragosus* presented by Smith (1991) is based on shell features (mainly number of ribs: 9 or 10 for *N. nodosus* and 7 or 8 for *N. fragosus*; finer macrosculpture and greater tendency to develop nodes on both valves of *N. fragosus*, and umbonal angle) (Table 25.1). In this manner, descriptions given by Abbott (1974), Eisenberg (1981), Abbott and Dance (1990), Rios (1994) and Lodeiros et al. (1999) included what is presently recognised as two distinct species (*N. nodosus* and *N. fragosus*) as being “*Lyropecten nodosus*”. These studies also report the geographic distribution of “*L. nodosus*” combining the range of both Atlantic species of *Nodipecten*, in depths from 35 to 150 m. Specimens of *N. nodosus* collected in Brazil follow the descriptions given by Smith (1991), except that specimens displaying bulbous nodes also on the right valve were occasionally observed (Rupp, pers. obs.).

In the present review, we follow the taxonomy according to Smith (1991), also in agreement with Waller (pers. comm., Smithsonian Institution) and Peñia (2001). Note, however, should be taken that taxonomic distinction of both species has been made solely on shell morphology. Further studies on genetic characterisation of different

Table 25.1

Morphological characteristics of *Nodipecten nodosus* and *N. fragosus* (from Smith 1991).

Feature	<i>N. nodosus</i>	<i>N. fragosus</i>
Number of ribs	9–10	7–8
Valve microsculpture	coarser	finer
Umbonal angle	95° in juveniles 105° in adults	86–94°
Nodes	Less tendency to develop large bulbous nodes; right valves lack nodes	Tendency to develop nodes on all ribs of both valves
Exterior colours	Red, orange, brown, purplish or mottled	Orange to reddish brown

species of *Nodipecten* and *Lyropecten* using molecular techniques may change the current view.

According to Smith (1991) *N. nodosus* is widespread in shallow tropical waters in the Caribbean, south of the Greater Antilles, the Virgin Islands, eastern Antilles, eastern Central America south of the Yucatan Peninsula; eastern Panama to Colombia and Venezuela, and discontinuously as far south as Rio de Janeiro state (Brazil). However, the southern distribution limit of *N. nodosus* is further south than Rio de Janeiro, reaching warm-temperate waters off Santa Catarina State (Rupp, pers. obs.). Except for a reference to Baía de Todos os Santos (Bahia, Brazil) (Smith 1991), and Recife (E. Rangel, pers. comm.) there are no other references for *N. nodosus* in the North and Northeast regions of Brazil. Rios (1994) also includes Ascension Is. in the geographic distribution of "*Lyropecten nodosus*". Bathymetric data are few for *N. nodosus*. According to Smith (1991), live organisms have been collected from 10–15 m. Rupp (1994, 1997) have collected *N. nodosus* in depths ranging from 6 to 30 m off Arvoredo and other islands in the vicinity of Santa Catarina island, (SC) Brazil (Fig. 25.3).

25.2.2 Ecology

Aspects of biology and ecology of *Nodipecten* spp. have been the subjects of few studies. According to Smith (1991), specimens of *Nodipecten* spp. were rarely observed alive, and most of her suppositions about this genus have been deduced from shell features or obtained through studies with other pectinids. Since Smith's (1991) publication, a few studies have been undertaken on *N. nodosus* (Brazil, Colombia and Venezuela) and *N. subnodosus* (Mexico), but mainly pertaining to issues related to aquaculture. For *N. nodosus*, no data are available about growth patterns in wild populations, life span, recruitment, mortality, or spatial distribution. The physiology and ecology have not yet been subjects of detailed studies.

Wild *Nodipecten nodosus*, as large as 17.8 cm, have been collected in Brazil (Rupp, pers. obs.) and it is considered within the group of living giant pectinids (Smith 1991). Considering the patterns for scallop life history described by Orensanz et al. (1991),

Figure 25.3. Map locating Arvoredo and Santa Catarina island, off Santa Catarina State (SC), Brazil.

N. nodosus can probably be included within the group of long-lived, iteroparous, large size species, which includes most of the commercially important scallops from temperate regions. Yet, it should be noted that, with regard to longevity, no published information is available.

In Brazil, *N. nodosus* inhabits mainly subtropical waters, and there is no information of populations occurring in the North and Northeast regions. The southern limit of distribution (Santa Catarina State - Lat. 27° S; Long. 048° W) is about 450 nautical miles southwest of Cabo Frio (RJ) (Lat. 23° S; Long. 042° W), which is considered the biogeographic boundary of the Western Atlantic Tropical Zone, and the distribution limit for many tropical marine species (Briggs 1995). The Brazilian southeast coast (Fig. 25.1), between Cape São Tomé (Lat. 22° S; Long 041° W) (RJ) and Cape Santa Marta (Lat. 28° 37' S Long. 048° 50' W) (SC) (Brandini 1990), is the region where populations of *N. nodosus* have been recognised, and where fisheries and aquaculture have been carried out, being included within the Western Atlantic warm-temperate biogeographic Region (cf. Briggs 1995).

The Brazilian southeast coast is seasonally influenced by different water masses. The oceanographic structure of this region is quite complex, but macro-scale oceanographic patterns have been identified (Emilsson 1961; Matsuura 1986; Castro and Miranda 1998, Sunyé and Servain 1998). As a generalisation, during summer to mid-autumn neritic waters are influenced by warm and oligotrophic waters of Brazil Current (tropical waters), which penetrates over the continental shelf. During winter, the area is mainly influenced by coastal advection of cold, low salinity and phytoplankton-rich waters of sub-Antarctic origin. Furthermore, from October–November to April, intrusions of cold and nutrient rich South Atlantic Central Water (SACW) into the bottom layers over the continental shelf have been reported to create a strong stratification in the water column influencing the inner shelf. This event leads to the formation of a strong thermocline creating subsurface phytoplankton maxima (Brandini 1990; Castro and Miranda 1998; Borzone et al. 1999). This temporal and spatial pattern in which food availability tend to vary in an opposite manner with temperature, is different from those described for most temperate and boreal regions, and can affect coastal aquaculture sites in Santa Catarina, having important influences on growth of scallops under culture conditions (Rupp 2003).

The main shell features of *Nodipecten* spp. are the prominent nodes and ledges. Under culture conditions in subtropical waters of southern Brazil, no evidence was found to support a relationship of node formation to variability in environmental factors or reproductive events, and the ecological significance of the hollow nodes is presently unclear. Furthermore, shell growth rings, commonly used as an age indicator in temperate scallops, are not clearly distinguishable in *N. nodosus*, except for disturbance rings caused by handling during thinning procedures, under culture conditions. Therefore, shell rings conveniently used as age estimators for temperate scallops (e.g., MacDonald and Thompson 1985a) are not useful for *N. nodosus*.

Unlike other scallops, which aggregate in economically valuable beds or banks (*Pecten maximus*, *Placopecten magellanicus*, *Argopecten irradians*, among others), *N. nodosus* is not gregarious. Rupp (pers. obs.) has found adult *N. nodosus* off Arvoredo Island (Brazil) at the limit between rocks and sandy or gravel bottoms, often byssally attached to the rocks. They are found particularly inside small rocky caves and crevices, or on sandy or calcareous patches adjacent to rocks. *N. nodosus* are usually found far from each other, but clumps of up to 3 or 4 animals have been observed, sometimes within the same cave. Shells are typically covered by epibionts and sediment, which provide camouflage, making them difficult to be found by inexperienced eyes. Juvenile *N. nodosus* have not been found in the same water depths as adults (Rupp, pers. obs.), as it is also reported for *N. subnodosus* (Smith 1991). Juvenile *N. subnodosus*, for example, have been found attached to spiny scallops (*Spondyllus princeps*) collected with deep trawl nets (40 m) (Félix-Pico et al. 1999). For *N. nodosus*, the question still remains whether the juveniles are highly cryptic or whether they occur in deeper waters.

A natural predator of *N. nodosus* in South Brazil is *Octopus vulgaris*. Octopus caves are often surrounded by several empty scallop shells, and octopuses preying upon scallops have been observed during underwater surveys (Rupp, pers. obs.). A characteristic of shells preyed by octopus is the presence of one or both auricles broken.

With regard to adductor muscle mass, wild *N. nodosus* of about 120–140 mm in shell height, from a population off Arvoredo Island, yield muscle wet mass of about 30–45 g (Rupp, unpubl.) and reach a maximum size of 17.8 cm. In the southern Caribbean region wild *N. nodosus* of about 120–140 mm yield muscle wet mass of about 18 g (Lodeiros et al. 1998) and the largest size reported is about 15 cm (Lodeiros et al. 1999). In southeastern Brazil, wild *N. nodosus* tend to have a larger shell size and adductor muscle weight and have heavier and thicker shells than *N. nodosus* from Margarita Islands, Venezuela (Rupp, pers. obs.). According to Sebens' model (Sebens 1982) relating the maximum size of suspension feeders and habitat suitability, animals living in environments resulting in lower physiological stress and/or supplying higher food availability, display a larger maximum size. This suggests that conditions in the subtropical environment of southern Brazil may be more suitable for scallop growth than the tropical areas of the Caribbean. However, genetic differences between these latitudinally separated populations should not be ruled out.

25.2.3 Reproduction

Information on the reproduction of *N. nodosus* is limited. *N. nodosus* is a simultaneous functional hermaphrodite (Rupp 1994). A study of the variation of the gonosomatic index (GSI) (wet weight) of a population off Arvoredo Island (Brazil) suggested a partial and asynchronous pattern of gamete release throughout the year, and higher GSI was recorded during late spring (November–December) (Manzoni et al. 1996) (Fig. 25.4). Lower reproductive activity was recorded during the winter (June–August), when a lower GSI was associated with periods of lower water temperatures. On the other hand, Manzoni and Banwart (2000) found higher gonosomatic indices of *N. nodosus* under culture conditions during winter months concomitant with lower water temperatures, but the asynchronous pattern of reproduction was again evidenced. It is possible that the previous results of Manzoni et al. (1996) were affected by the fact that temperature was recorded at 8 m but scallops were collected in a wide range of depths, from 8 to 30 m. From late spring to early autumn waters off Santa Catarina State can be influenced by subsurface intrusion of cold and phytoplankton-rich South Atlantic Central Water (SACW), which can reach depths up to 15 m (Borzone et al. 1999). Therefore, it is possible that scallops were collected below the thermocline, where they were exposed to temperatures lower than those recorded at 8 m, but higher phytoplankton abundance. As the reproductive cycle of scallops is a complex function of temperature and food availability (MacDonald and Thompson 1985b), the relationship among these factors and reproductive activity of this subtropical population of *N. nodosus* requires further investigation.

In the Caribbean region, Vélez et al. (1987) studied the seasonal variation in biochemical composition of Venezuelan scallops and suggested that *Nodipecten* (= *Lyropecten*) *nodosus* spawns throughout the year in an asynchronous fashion, with the period of greatest reproductive activity between August and February. In this geographic region, higher temperatures and lower phytoplankton abundance are generally found from August to December (Lodeiros and Himmelman 1994, 2000; Vélez et al. 1995).

Figure 25.4. Gonosomatic index (G.S.I. $\pm$ SD) of *Nodipecten nodosus* sampled at Arvoredo Island, Santa Catarina State, Brazil, from January 1991 to January 1992, (From Manzoni et al. 1996).

Coronado et al. (1991) studied the genetic variability of some Venezuelan scallops, and suggested that *N. nodosus* has a much lower genetic variability compared to other scallops. Self-fertilisation is hypothesised to account for the low variability in natural populations (Coronado et al. 1991). For *N. nodosus*, the diploid number of chromosomes is reported to be 38, with 4 pairs metacentric, 5 pairs submetacentric, 7 pairs subtelocentric and 3 pairs telocentric chromosomes (Basoa et al. 2000). Thirty eight chromosomes, also reported for *Euvola ziczac*, agrees with the diploid numbers reported in other pectinid species such as *Pecten maximus*, *Placopecten magellanicus* and *Patinopecten yessoensis* among others (citations in Basoa et al. 2000). A comparison of self-fertilised orange *N. nodosus* and cross-fertilised orange and brown specimens undertaken by Alfonsi and Pérez (1998) indicated that self-fertilisation adversely affected survival, but, interestingly, favoured growth.

25.2.4 Aquaculture

25.2.4.1 Status

The recent success of bivalve mariculture in Santa Catarina State (for oysters, *Crassostrea gigas* and mussels, *Perna perna*), is increasing expectations for the scallop *Nodipecten nodosus* as the next candidate for the aquaculture industry. Although scallop

culture is a promising activity, resources to study and promote its establishment have been limited, and to date there has been no official plan to foster its development.

Although initial studies on feasibility of culture of *N. nodosus* date from 1990 (Manzoni 1994; Rupp 1994), only recently, through internationally funded projects [European Union: Project INCO Scallop (1997–2000) and Canadian International Development Agency (Brazilian Mariculture Linkage Project - BMLP): Project Biology and Mariculture of *Nodipecten nodosus* 2000–2002)] has it been possible to advance the studies at the Laboratory for the Culture of Marine Molluscs (Federal University of Santa Catarina). The main objectives have been to overcome the primary constraint to the development of scallop culture: a sustained seed supply. Studies aiming to optimise larval and postlarval survivorship and growth in the hatchery, as well as the assessment of appropriate environmental conditions for sea-based nursery have been recently carried out (Pereira 2000, Bem et al. 2001a,b, Rupp et al. 2003a,b).

There are presently four institutions involved with aquaculture of *N. nodosus* in Brazil. At the Federal University of Santa Catarina (UFSC) research focusing on development of hatchery techniques, ecophysiology and experimental culture have been carried out. The UNIVALI (Universidade do Vale do Itajaí), a private university located in Santa Catarina State, is involved in experimental growout, and the establishment of an experimental hatchery is underway. Also in Santa Catarina, the State Government Agricultural Extension Agency (EPAGRI) is developing experimental cultivation of scallops in collaboration with mollusc growers. In Angra dos Reis, State of Rio de Janeiro, the IEDBIG (Instituto de Ecodesenvolvimento da Baía de Ilha Grande), a private foundation, funded by PETROBRAS (Brazilian Petroleum Company) and FURNAS (nuclear power plant), have been attempting commercial hatchery production of *N. nodosus* seed (Avelar 2000). Also, in Angra dos Reis, two private foundations have previously attempted to produce seed of *N. nodosus* (1995–1997), but activities were discontinued. Presently there are no commercial ventures growing *N. nodosus* in Brazil, and scallop aquaculture is still in its infancy at an experimental to pilot-scale.

25.2.4.2 Culture technology

25.2.4.2.1 Wild seed collection

Settlement of post-larval *N. nodosus* on artificial collectors deployed at Arvoredo Island (1991–1992) took place throughout the year, but in fairly low numbers (total 100 spat) compared with another pectinid (*Leptopecten bavahyi* – 18,315 spat) that also settled on the same collectors (Manzoni 1994). As well, *Euvola ziczac* and *Aequipecten tehuelchus* settled in low numbers (87 and 14, respectively). The low spat settlement associated with partial and asynchronous pattern of reproduction, the low-density populations widespread in a large geographic area, along with the complex hydrodynamics in the region, suggest that wild spat collection is unlikely to be a reliable source of *N. nodosus* seed for aquaculture. Therefore, hatchery production was proposed as the alternative source of spat to sustain potential aquaculture activity, and studies were oriented in that direction.

25.2.4.2.2 Hatchery production

Initial results with regard to larval production of *N. nodosus* in hatchery, were presented at the 9th International Pectinid Workshop, in Nanaimo, Canada, in 1993 (Rupp and Poli 1994). Induction of spawning using thermal stimulation and UV treated seawater, usually results in high quantities of oocytes (2.2–21.6 million per scallop, depending on size), within one to two hours, when gonads are sufficiently ripe. Sperm is usually released prior to oocytes. In four spawnings, when a total of 27 scallops were induced to spawn, 72.7% initially released sperm. Subsequently, 31.5% started to release oocytes, 22.7% released exclusively sperm, and 18.5% alternated release of oocytes and sperm, or released both gametes simultaneously. Of the ones that started releasing oocytes (27.3%), 18.2% subsequently released sperm and 9.1% released oocytes only (Rupp 1996). Considering that 68.2% of the induced scallops released gametes of both sexes and the switch from one sexual product to another is seldom preceded by an interval, a certain degree of self-fertilisation is difficult to avoid (Rupp 1996).

The ontogenic development of larvae follows a similar pattern as described for other pectinids (Table 25.2). Mean oocyte diameter ranges from 60–68 μm . “D” shape veligers are completely formed at 22 to 24 h after fertilisation at 25 to 27°C, and shell lengths are about 100 μm (Rupp 1994). The growth relationship between larval shell dimensions can be expressed by the allometric equation $H = 0.322 L^{1.198}$, where H = shell height (μm) and L = shell length (μm) ($r^2 = 0.99$) (Rupp 1994). Larval period ranges from 14 to 23 days and average larval growth rates vary from about 6–8 $\mu\text{m day}^{-1}$ depending on culture conditions. Larval cultures are carried out using “standard” hatchery techniques, in tanks from 100 to 2,500 L depending on the experiment, and water changes are undertaken daily or every other day. Feeding typically consists of a mixed diet of flagellates and diatoms in concentrations ranging from 10–30 cells μL^{-1} . At the end of the larval culture, pediveligers settle and attach to artificial substrates (Netlon™, polycarbonate, and polyethylene) when dissoconch shell begins to form (Rupp 1994, 1997). Larval culture techniques for *N. nodosus* and other scallops from the Iberoamerican region have been recently reviewed by Uriarte et al. (2001).

Hatchery production of spat on an experimental-pilot scale is currently feasible on a routine basis. At the Laboratory for the Culture of Marine Molluscs, Federal University of Santa Catarina (Brazil) larval retrievals from “D” larvae to metamorphosis typically ranged from 0 to 14%, until 1997. The term retrieval here reflects not only the number of surviving larvae, but also excludes live larvae intentionally eliminated to reduce culture densities and select fast growing larvae. Table 25.3 shows the percent retrievals of “D” larvae, and pediveligers in selected larval cultures. The high larval mortalities, and sometimes total loss, had been associated with bacterial pathogenicity (Bem 1999). Isolation and identification of *Vibrio* strains from larval cultures have been carried out, as well as the development of alternatives to increase survivorship in larval cultures. Several bacterial strains were isolated from healthy and diseased larval cultures of *N. nodosus*. A highly pathogenic strain of *Vibrio* sp., (identification in progress), resulted in 100% mortality within 48 hours of inoculation during pathogenicity tests against *N. nodosus* larvae. Further, two novel *Vibrio* species (*V. neptunius* and *V. brasiliensis*) isolated

Table 25.2

Larval development of *Nodipecten nodosus* (from Rupp 1994).

	Temperature (°C)	Mean dimensions (µm)	Period after fertilisation
Oocytes	27	60–68	
Trochophore	27		10–12 hours
“D” larvae	27	length: 98.65 height: 76.52	22 hours
Umbo stage	26–27	length: 146.18 height: 128.01	7 days
Eyed pediveligers	23–26	length: 186.51 height: 167.77	14 days
Settlement	23–26	length: 207–214	14–19 days

from larval cultures of *N. nodosus*, at LCMM have been recently described (Thompson et al. 2003). The assessment of pathogenic activity of these new *Vibrio* spp. on scallop larvae should be the subject of further investigations. As a result of the identification of the major sources of larval mortality, strict hatchery sanitation procedures have recently resulted in an increase of larval survivorship leading to retrievals of up to 22% (Table 25.3), noting that a large percentage of live larvae were eliminated to reduce densities. The high susceptibility of scallop larvae to vibriosis in relation to other bivalves has been proposed to be caused by the relatively immature immune system in larval pectinids (Luna-Gonzales et al. 2002). Furthermore, granular hemocytes, the main cells actively involved in the immune defence in oysters and mussels (Cheng 1981; Hine 1999), have not been detected in adult lion's paw scallop *Nodipecten nodosus* (Vargas-Albores and Barraco 2001), which may also explain the high susceptibility of post-metamorphic life stages.

The artificial collectors with small spat attached can be transferred to the field 2 to 5 weeks after settlement, and 4–6 weeks later the spat attain a size of about 5–7 mm. The percent retrieval of 1–2 mm post-larvae and 5–10 mm juveniles are shown in Table 25.4. Land-based nursery techniques are costly, labour intensive and demand large volumes of cultured microalgae, due to the increasing feeding demand of growing scallops. Improvements are needed during nursery culture for a successful commercial-scale production, and the approach of early transfer of the spat to the field-based nursery is being investigated. Studies on the effect of the size at deployment, depth and seasonal variability of environmental factors during sea-based nursery on growth and survivorship of spat are underway (Rupp et al. 2003a, b).

With regard to broodstock conditioning, Rupp et al. (1997) concluded that *N. nodosus* maintained in the laboratory at temperatures of 17–18°C resulted in a higher percentage of spawning and higher quantities of oocytes released than the ones maintained at 25°C. Broodstock conditioning at low temperatures has been successfully accomplished in several trials for purposes of experimental seed production (Rupp, unpubl.).

Table 25.3

Number of oocytes released, "D" larvae and settling pediveligers and respective percent retrievals, obtained in some experimental larval cultures at the Laboratory for the Culture of Marine Molluscs, UFSC, Brazil.

Year	Number of oocytes	Number of "D" larvae recovered and used	% retrieval of "D" larvae in relation to oocytes	Number of settling pediveligers	% retrieval of pediveligers in relation to "D" larvae	Reference
1992	1.44×10^6	1.26×10^6	87.5%	76,000	6.03%	Rupp 1994
1996		11.06×10^6		211,000	1.9%	Rupp 1997
1996	12.6×10^6	9.52×10^6 used; 6.00×10^6	75.5%	750,000	12.5%	Rupp 1997
1996		5.58×10^6		350,000	6.27%	Rupp 1997
2000		49.2×10^6		8,775,000	17.84%	Unpubl.
2001		8.6×10^6		1,683,000	22.14%	Unpubl.
2001		17.1×10^6		2,366,000	13.18%	Unpubl.

25.2.4.2.3 Growout

Growout experiments with *Nodipecten nodosus* in the subtropical marine environment of Santa Catarina have been limited. From initial suspended culture trials held in 1991 and 1992, in Arvoredo Island, growth rates varied from 5.5 to 16.7 mm month⁻¹ depending on scallop size, with individuals reaching the size of 104 mm (from 10 mm spat) within 10 month of culture, resulting in an average growth rate of 9.4 mm month⁻¹ (Manzoni 1994). These are amongst the fastest growth rates recorded for scallops (cf. Bricelj and Shumway 1991). Growth was determined by means of shell dimensions and 100% survival was attained. It should be noted that these experiments were carried out at depths of 8 m, with a limited number of scallops (2–10) and at a reduced density per

layer in the lantern nets. In spite of low sample size, this study gives an indication of the high growth potential of *N. nodosus*, if suitable environmental conditions are provided. Manzoni and Marenzi (1997) reported an experimental culture of *N. nodosus* in Itapocoroi Cove (Santa Catarina) in which scallops reached 70 mm within 9 month (from 10 mm spat), indicating an average growth of about 6.6 mm month⁻¹, but mortality data were not presented. As well, in growout trials held at Pinheira Cove (Santa Catarina) using surface long lines in 1996 by Rupp (unpubl.) scallops reached about 66 mm within 10 month of culture (average growth rate 5.2 mm month⁻¹, and mortalities of approximately 60%). In this trial, heavy fouling colonisation on scallop shells and culture devices was an important factor affecting growth and survival of cultured scallops. A list of the most conspicuous epibionts observed on scallops cultured at Pinheira Cove is presented in Table 25.5. Although environmental parameters other than temperature had not been assessed in those studies, it is clear that the more oceanic conditions of waters off Arvoredo Island (located about 10 miles offshore) are more suitable for scallop growth than coastal embayments. Studies on the effects of environmental factors on growth and survivorship of *N. nodosus* on a coastal aquaculture site off Porto Belo island, are currently underway (Rupp et al. 2004a, b).

In Rio de Janeiro state (Brazil), scallop growth trials have been attempted but to date, limited information is available. Avelar (2000) reports that *N. nodosus* cultured at different densities off Ilha Grande, reached a mean shell height of 83 to 93 mm (from 10 mm spat) within one year. Survivorship ranged between 84 and 90%. In Ilha Grande Bay high mortalities have also been recorded in some periods of the year and it has been suggested to be caused by high temperatures concurrent with spawning events and possible low phytoplankton abundance (Rangel, pers. comm., Aquacultura do Norte Nordeste Ltda).

Lodeiros et al. (1998) reports experimental suspended culture of *Nodipecten* (*Lyropecten*) *nodosus* in the Caribbean Sea (Venezuela) in which growth rates progressively decreased with depth. At 8 m, scallops attained fast growth rates, but total mortality after 7 months of culture was attributed to heavy fouling colonisation on shells. In addition, other factors such as high temperature and harmful algal blooms may have accounted for the high mortality. At 31 m, slow growth and total mortality was associated with low phytoplankton abundance. The best results were recorded at 21 m, where 50% mortality was attained and the maximum size after 10 months of culture was about 5.5 cm. Vélez et al. (1997) reports a cumulative growth of 50 mm within 8 months for *N. nodosus* in suspended culture in Venezuela, but high mortality at the end of the experiment was associated with harmful algal blooms.

As previously mentioned, culture trials of *N. nodosus* on an experimental – pilot-scale have been undertaken in coastal embayments in Santa Catarina State, but growth rates were reduced when compared to growth trials undertaken in more oceanic conditions (Arvoredo Island). Even so, the growth rates obtained in inshore areas are still higher than those reported for other scallops currently cultured at a commercial level elsewhere. The catarina scallop, *Argopecten ventricosus*, reaches the commercial size of 5.7 cm in 11 months in Mexico (Maeda-Martinez et al. 1997) and bay scallop, *Argopecten irradians*, reaches a market size of 50 to 60 mm within one year in China (Guo et al. 1999).

Table 25.5

Conspicuous epibionts observed on shells of *Nodipecten nodosus* cultured in suspension at Pinheira Cove in 1996 (Rupp, unpubl.).

Phylum	Class	Species	Remarks
Porifera		Not identified	Yellow colour, shell-borer
		Not identified	Purple colour, tends to cover shells
Cnidaria	Anthozoa	<i>Bunodosoma</i> sp.	
	Hydrozoa	<i>Ectopleura</i> sp.	
Platyhelminthes	Turbellaria	<i>Stylochoplana</i> sp.	
Mollusca	Bivalvia	<i>Ostrea equestris</i>	
		<i>Crassostrea rhizophorae</i>	
		<i>Perna perna</i>	
		<i>Leptopecten bavayi</i>	
		<i>Lithophaga patagonica</i>	
		<i>Thais haemastoma</i>	
	Gastropoda	<i>Cymatium parthenopeum</i>	
		Egg masses of gastropods	
		<i>Polidora websterii</i>	
		Not identified	Green colour
Annelida	Polychaeta	Not identified	Red colour
Crustacea	Cirripedia	<i>Balanus</i> sp.	
	Malacostraca		Several species of the Orders Decapoda, Amphipoda and Isopoda
Bryozoa		<i>Bugula</i> sp. and <i>Schizoporella</i> sp.	
Chordata	Ascidacea	<i>Clavelina</i> sp. and <i>Styela</i> sp.	

Further, the large size and growth potential of *N. nodosus* indicates that when cultured under more suitable environmental conditions, and as soon as experimental work proceeds leading to adequate culture strategies, this species may yield scallops of 10 cm, in a period much shorter than the large and high valued pectinids cultured in temperate waters (e.g., *Placopecten magellanicus*, *Pecten maximus* and *Patinopecten yessoensis*) which take 2 to 5 years to reach commercial size. Therefore, developing new strategies for culturing *N. nodosus* outside shallow protected areas should be pursued. In southeastern Brazilian coast, the continental shelf is very wide and subsurface long-lines could be deployed in depths from 20 to 50 m without interfering with navigation, providing vast areas for aquaculture developments. Furthermore, if adequate strategies are employed, especially to reduce fouling, the production of smaller size scallops (5–6 cm) in a short period of time (8–9 months) in coastal protected areas, may be commercially feasible. Bottom culture is another potential alternative for culture of *N. nodosus*, but to date, no

information is available on this approach in Brazil. Further studies on the cost-effectiveness of the different growout methods are needed to determine the economic feasibility of culture of *N. nodosus* in Brazil.

25.2.4.2.4 Constraints

Seed supply has been the major constraint to the development of scallop culture in Brazil. Unlike most of the cultured scallops, on which industry can rely upon wild-collected and hatchery-produced seeds, the only source of juvenile *N. nodosus* to sustain aquaculture is hatchery production. The total dependence on hatcheries makes essential the establishment of a reliable and consistent technology in order to supply seed in high quantity and quality. Although *N. nodosus* larvae are amenable to culture, they are very sensitive to culture conditions and may be subject to mass mortalities due to pathogenic bacteria, as also reported in other pectinids. Developments in hatchery technology to improve water quality and produce high quality algal cultures, along with adequate hatchery sanitation, tend to lead to such reliable seed production. For sea-based cultivation the influence of environmental factors on growth and survivorship of *N. nodosus* during nursery culture and growout have to be considered, and site selection criteria have to be established based on ecophysiological parameters, in order to maximise production. Such constraints can be overcome in the near future if research efforts and institutional support are continued, and resources committed to the development of scallop culture in Brazil.

25.2.5 Fisheries and Marketing

The current market is mainly based on a small-scale fishery by recreational SCUBA divers or occasionally by fisherman. *N. nodosus* is the subject of anecdotal capture off coastal islands in the States of Rio de Janeiro, São Paulo, Paraná, Santa Catarina and Espírito Santo, supplying small local markets and fine restaurants. In some instances, the restaurant owners are the ones who dive to collect the scallops. There are no capture/production statistics available, but considering the low densities and patchy distribution of populations, wild stocks would not sustain any large-scale exploitation. *N. nodosus* is mentioned by Ostini and Poli (1990) as having threatened stocks due to intensive capture during summer tourist seasons. Although it may be true in some areas, to date no stock assessment of wild *N. nodosus* populations has been carried out and no conclusive statement can be made considering the spasmodic fluctuations characteristic of scallop populations. *N. nodosus* is the mollusc having the highest market value in Brazil and unit price can surpass US\$ 5.00 for large whole scallops (>12 cm), including shells, depending on the region and season. The capture is more intense during the tourist season (summer), and its high value is stimulated not only by the large adductor muscle, which is served as a fine delicacy, but also by the ornamental appeal of the shells along with their scarcity of supply. There is also a parallel market for the large shells, which are refractory and used to prepare and serve seafood dishes in restaurants. Rare specimens with yellow or orange shells reach high prices in the collectors' market. Occasional small-scale

aquaculture production yielded scallops from 6–7 cm, which were sold for about US\$ 1.00 per whole scallop. No marketing surveys have been undertaken to date for the potential of *N. nodosus*, but considering the large market for seafood in general and the high demand for other bivalves (oysters, mussels and clams), in which the demand has been higher than the supply, there is a large potential market for high quality cultured *N. nodosus* in Brazil. This underdeveloped market has been constrained by the limited availability of the product and high prices of imported scallops.

An area with one of the most notable stocks of *N. nodosus* is Arvoredo Island, Santa Catarina State (Lat. 27° 17' S, Long. 048° 22' W) (Fig. 25.3), where capture by recreational divers was common until recently. Following an increase in environmental awareness, and the need to protect coastal environments, Arvoredo Island and its adjacent waters have been declared a Biological Preservation Area by the Instituto Brasileiro do Meio Ambiente (IBAMA), and the capture of organisms is now prohibited (BRASIL 1990), unless for research purposes.

25.2.6 Future Prospects

Hatchery technology for production of *Nodipecten nodosus* on an experimental – pilot scale is well advanced in Brazil. The transition to a sustainable commercial production will mainly depend upon continued research in order to overcome some remaining constraints and on logistic improvements in the Brazilian hatcheries. Hence, hatchery technology should not preclude further developments of scallop culture in Brazil if appropriate steps are taken to establish this new and promising activity, and private ventures are created to increase production. If future developments of scallop aquaculture are directed to the utilisation of open marine areas on the continental shelf at depths from 20 to 50 m, then legal aspects of coastal zone management will have to be addressed. Likewise, before large scale aquaculture is attempted in this area, research is needed to assess the effects of the oceanographic dynamics on scallop growth and survival. The recent success and development of oysters and mussels culture in Brazil created a positive political and social climate for further development of bivalve aquaculture, and *N. nodosus* is the next obvious candidate. The large size, commercial value and potential market are increasing interest of mollusc growers wanting to diversify their products and of new entrepreneurs wanting to carry out bivalve aquaculture. Thus, it appears that the commercial development of *N. nodosus* culture is imminent.

25.3 *Euvola (Pecten) ziczac* – BIOLOGY, AQUACULTURE AND FISHERIES

25.3.1 Taxonomy and Distribution

Among the marine molluscs collected by Helmut Sick off Ilha Grande, Brazil, in 1943–44, is *Pecten (Euvola) ziczac* (Haas 1953). The zigzag scallop, *Euvola ziczac* (Linnaeus, 1758) (cf. Waller 1991) is known in Portuguese as “vieira”. The upper valve (left) is flat and displays fine zigzag markings of white and brown. The lower valve is very deep and convex, with very low ribs and radial and concentric grooves, displaying

colours varying from white to brown or orange brown (Abbott 1974; Dance 1990). *Euvola* (= *Pecten*) *ziczac* occurs in the Western Atlantic, from North Carolina and Bermuda, to Santa Catarina State, Brazil (Rios 1994).

25.3.2 Ecology

Wild *Euvola* (= *Pecten*) *ziczac* are reported to reach up to 100 mm in shell height (Dance 1990). Its depth distribution varies according to the geographic area. It is reported to range from 15 to 75 meters in sandy and calcareous algae bottoms by Rios (1994). On the other hand, Abbott and Dance (1990) report its depth range from 1 to 40 m. Vélez and Lodeiros (1990) report natural beds of *E. ziczac* between 6 and 10 m in Venezuela, particularly in areas affected by coastal upwelling. In the southeastern Brazilian coast, *E. ziczac* aggregates in beds between 30 and 50 m, off the States of São Paulo, Paraná and northern Santa Catarina in sandy bottoms or sandy and broken shell bottoms, being absent on muddy substrates (BRASIL 1976). In this area, the most frequent size of the scallops was about 85 mm of shell height, but individuals up to 95 mm have been collected (BRASIL 1976). To date, no data are available on longevity of *E. ziczac* in wild populations, but Vélez et al. (1995) suggests, from a projection of growth curves for scallops cultured in partly buried cages, that *E. ziczac* could attain 70–80 mm in about 1.5 years in the wild. *E. ziczac* is a recessing scallop, and in its natural habitat is usually buried with a thin layer of sand covering the upper valve, which is slightly concave, preventing the colonisation of biofouling (Vélez et al. 1995).

25.3.3 Reproduction

Euvola ziczac is a hermaphroditic bivalve, which in southeastern Brazil, reproduces throughout the year in an asynchronous and continuous manner, but with variable intensities (Peres 1981). Higher spawning activity was recorded during summer, autumn and spring. On the other hand, Vélez et al. (1987) studying the biochemical composition of the gonads of *E. ziczac* of a population off Venezuela, report a synchronic bimodal pattern of reproduction, with two peak periods of spawning: from April to May, and from August to September, displaying a pattern typically different of most tropical bivalves, which tend to reproduce continuously. In this Venezuelan population, gametogenesis, accumulation of reserves and gonad growth are associated with periods of minimum temperature and increased primary productivity associated with upwelling events (Vélez et al. 1993). Peres (1981), in a histological study of the reproductive cycle of *E. ziczac* from a population off southeastern Brazil, indicated that *E. ziczac* show a high percentage of protandric individuals in spring, while in summer and autumn proterogynous individuals predominate. In this manner, although Vélez et al. (1990) indicate that *E. ziczac* from a Venezuelan population is a simultaneous hermaphrodite, Peres (1981), suggest that simultaneous hermaphroditism was not recorded in the population from southeastern Brazil. Such reproductive behaviour is not common in monoecious bivalves (Fretter and Graham 1964). Furthermore, Peres (1981), hypothesise that, as a consequence of this phenomenon, self-fertilisation is infrequent in this species.

Inductions of spawning of *E. ziczac* from the Brazilian population in the laboratory should clarify whether simultaneous hermaphroditism and self-fertilisation can occur.

25.3.4 Aquaculture

25.3.4.1 Status

To date no studies have focused on aquaculture of *E. ziczac* in Brazil. Such studies have been primarily oriented towards *Nodipecten nodosus*, due to the larger size and higher commercial interest, as well as due to the availability of broodstock to induce spawning in the hatchery. While *N. nodosus* can be readily collected by diving on coastal islands and transported quickly to the hatchery (Rupp 1994), *E. ziczac* is harvested as a by-catch product of commercial shrimp trawlers, being stored on ice where they dehydrate and die quickly (Morais and Kai 1980), thus, making it difficult to obtain live broodstock for husbandry practices.

25.3.4.2 Culture technology

25.3.4.2.1 Wild seed collection

Occasional settlement of spat of *E. ziczac* (up to 10–20 per collector) have been recorded on monofilament collectors holding hatchery produced spat of *N. nodosus*, after being deployed to the nursery phase in the sea (Rupp, pers. obs.). In addition, Manzoni (1994) reported settlement of 87 individuals on monofilaments off Arvoredo Island during one year. Due to the anecdotal nature of these results, no seasonal pattern can be discerned. Although low numbers for commercial purposes, wild collected spat could be grown until adult size and further used as broodstock for reproduction in the hatchery and seed production. In Venezuela, Vélez and Lodeiros (1990) indicated that wild spat collection of *E. ziczac* was also difficult to obtain. In Bermuda, Manuel (1999) reports that settlement of *E. ziczac* on artificial collectors takes place between October and June with evidence of a bimodal pattern, the larger peak occurring between February and April and the other peak in November–December.

25.3.4.2.2 Hatchery production

Studies pertaining to hatchery seed production of *E. ziczac* have been undertaken in Venezuela (Vélez and Freitas 1993) and in Bermuda (Sarkis 1995). Larvae are amenable to culture using standard hatchery techniques and the larval period takes about 10 to 12 days at 26°C and densities of 5–10 larvae/mL (Vélez and Freitas 1993). Settlement can be carried out on plastic filaments and plastic plates deployed in upwelling or downwelling tanks. Spat were successfully transferred to the field when they reached at sizes of 1 and 3 mm. Whereas there are presently no commercial enterprises in Venezuela producing *E. ziczac* (Lodeiros, pers. comm.), commercial hatchery production of zigzag scallop is under way in Bermuda (Sarkis, pers. comm.). In Brazil, *E. ziczac* is considered

a potential candidate species for aquaculture, and as soon as culture of *Nodipecten nodosus* becomes established commercially, the hatchery technology available would be readily adapted to produce seeds of *E. ziczac* if a demand is raised from growers wanting to diversify their products.

25.3.4.2.3 Growout

Aquaculture studies focusing on growout stage of *E. ziczac* have not been undertaken in Brazil. In Venezuela, several studies have evaluated the biological feasibility of culturing *E. ziczac* in a tropical marine environment (See Lodeiros et al. Chapter 28).

25.3.4.2.4 Constraints

Several factors causing major constraints to culture of *E. ziczac* in suspension have been identified in a tropical environment, and bottom culture seems to be more suitable than suspension culture (See Lodeiros et al. Chapter 28). In the subtropical marine environment of Brazil, the effect of environmental factors on growth and survivorship of *E. ziczac* should be evaluated before commercial operations are attempted. As for *Nodipecten nodosus* aquaculture, development of *E. ziczac* will have to rely on hatchery production of seeds.

25.3.5 Fisheries

Fisheries targeting the zigzag scallop began in Brazil in 1972, when 12 t of scallops were landed in the State of São Paulo (BRASIL 1976). The identification of this unexploited resource gained the attention of the commercial shrimp fleet establishing a non-traditional fishery, which in subsequent years displayed variable yields, collapsing after 1986. Surveys undertaken in 1974 identified scallop beds off southern State of São Paulo, Paraná State and northern Santa Catarina, between latitudes 24° 26'S and 26° 20'S, in depths ranging from 20 to 50 m (BRASIL 1976).

From being a minor by-catch product of shrimp trawlers before 1972, *E. ziczac* started to be caught commercially and stimulated the possibilities of additional profits obtained by exporting this valuable product (Anonymous 1975). As soon as the scallop beds were identified, fishermen used the same type of shrimp otter-trawl nets with a few modifications to target scallops (Rebello Neto 1980). Fishery statistics, fleet characteristics and destination of production of *Euvola ziczac* have been reviewed by Pezzuto and Borzone (1997). According to official fishery statistics, a peak production reached about 3,799.0 tonnes in 1975, subsequently declining to 8.7 tonnes in 1980. Maximum landings of zigzag scallop were reported to occur in 1981, when 8,845.3 t were harvested, followed again by a decrease in production subsequent years. In 1986, production reached about 1.9 t. Since then, landings have been insignificant, returning to the condition of minor by-catch product of shrimp fisheries, but no official statistics are available (Pezzuto and Borzone 1997). Considering the period over which the fishery operated, Pezzuto and Borzone (1997) suggest that there is a cycle of 3–5 years in scallop

production. Recent surveys reported by Pezzuto et al. (1998) undertaken in the area where commercial scallop fisheries once took place, indicated that the yields were still low and the stocks are in a fragile situation. In nine cruises, yields ranged from 0 to a maximum of 35 scallops h^{-1} .

Scallop production in Brazil was completely directed to international markets, mainly as frozen muscle, generating an export value from 1973 to 1981 of US\$ 6 million according to official statistics from the Ministry of Agriculture. The price of muscle varied from US\$ 2.73 kg^{-1} in 1973 to US\$ 6.55 kg^{-1} in 1981. The main importers were the United States (58%) and France (36%) (Pezzuto and Borzone 1997).

25.3.6 Future Prospects

Interest in culturing *Euvola ziczac* has been limited in Brazil compared to *Nodipecten nodosus*, a species with high interest in commercial culture. The low interest in *E. ziczac* is due to its smaller size and lower commercial value, along with a lack of seed supply and constraints to culture *E. ziczac* in suspension, which is the main system currently used by mollusc growers in Brazil. If aquaculture of *E. ziczac* is to be developed in Brazil, it will follow advances on culture of *N. nodosus* as a demand from growers is created in order to diversify their product, and if trends are oriented towards the use of bottom culture techniques.

Considering that most of scallop stocks display a pattern of fluctuation classified as spasmodic (Orensanz et al. 1991), characterised by irregular pulses of high abundance followed by periods of scarcity or collapse, it is possible that the *E. ziczac* beds off the southeastern coast of Brazil could re-establish in the future. Although stocks of *E. ziczac* have fallen below levels commercially exploitable, pulses of successful recruitment could occur, leading to population levels attained when scallop fisheries once operated in Brazil. It is necessary, however, to protect the natural grounds from the fishing fleet, along with regulations and adequate fishery management, otherwise a complete collapse of this resource will be unavoidable.

ACKNOWLEDGMENTS

Results on aquaculture of *Nodipecten nodosus* summarised in the present review were obtained under a M.Sc. Scholarship (CNPq – Conselho Nacional de Desenvolvimento Científico e Tecnológico, Brazil) (1992–1994) and a RHAE/PIBIO – CNPq Technology Development Fellowship (DTI) granted to GSR (1994–1996). Research has also been supported by European Union - Project INCO Scallop (1997–2000) and Canadian International Development Agency - Brazilian Mariculture Linkage Project (BMLP) (2000–2002). Compilation and writing of this article was undertaken under a Ph.D. scholarship (CNPq) granted to GSR. T. Waller and E. Rangel kindly provided information for this manuscript. We thank the personnel of the Laboratory for the Culture of Marine Molluscs (LCMM) - Department of Aquaculture - Universidade Federal de Santa Catarina, for the co-operation and assistance on experimental work.

26.1 INTRODUCTION

When the first edition of this book was published over a decade ago, the only pectinid species commercially exploited in the southwestern Atlantic was the Tehuelche scallop, *Aequipecten tehuelchus* (d'Orbigny, 1846) (Orensanz et al. 1991). In the intervening time an industrial fishery developed for the Patagonian scallop, *Zygochlamys patagonica* (King & Broderip, 1832), whose potential value was highlighted in the first edition.

The fisheries supported by these two species are radically different from each other. The Tehuelche scallop is the target of small inshore fisheries in the gulfs of northern Patagonia, and involves dredging and commercial diving. In spite of the small volumes landed, these fisheries are of considerable significance for the local economies. The Patagonic scallop fishery, by contrast, is an industrial operation conducted by three or four factory trawlers that process the catch at sea. Catches in the order of 50,000 tons yr⁻¹, now rank this species among the most important scallop fisheries in the World.

Below we review knowledge about these two species, their fisheries, and experimental results that may have significance in the future development of aquaculture.

26.2 THE TEHUELCHES SCALLOP, *Aequipecten tehuelchus*

26.2.1 Biology

The Tehuelche scallop, *Aequipecten tehuelchus*, is distributed in the southwest Atlantic, from Rio de Janeiro (23° SL, Brazil) to northern San Jorge Gulf (45° SL, Argentine Patagonia), inhabiting sandy bottoms at depths below 130 m. This is one of the most studied bivalves from that region. Its anatomy has been minutely described (Ciocco 1992a, b, 1995a, 1998). The shell has 14–19 conspicuous ribs (Fig. 26.1).

Main annual growth rings (corresponding to periods of slow growth) are marked in late spring/early summer, and are related to spawning; winter rings are always weaker (Orensanz et al. 1985). Rings marked during the first year of life are often inconspicuous. Growth rings apparently facilitate settlement of the spionid polychaete worm *Polydora websteri* (Orensanz 1986). Ciocco (1990) confirmed that *Polydora* infection depresses growth rate, and showed that the intensity of the infection increases with age. Slow growth rate favours settlement of *Polydora* near the border of the shell; as a result, growth

Figure 26.1. Left: *Zygochlamys patagonica*; right: *Aequipecten tehuelchus*.

rings tend to be 'highlighted' by shell-borers (Orensanz et al. 1991; Fig. 26.3). Maximum reported shell height is 102 mm, but specimens larger than 90 mm are uncommon. Growth rings are also readable in the ligament (Astort and Borzone 1980). Maximum age recorded from growth rings is 11 years (San José Gulf), but scallops older than 8 years are rare.

The Tehuelche scallop is a simultaneous hermaphrodite (Christiansen and Olivier 1971), and is iteroparous. First spawning occurs at the age of one year, although energy allocation to reproduction is proportionally smaller in first-time spawners. Gonadal development is controlled by temperature (Orensanz 1986), with spawning occurring when temperature reaches 14–15°C (de Vido de Mattio 1984; Ciocco 1985). In both the San Matías and José Gulfs (Fig. 26.2) there is a partial spawning pulse in spring; pre- and post-spawning stages coexist over the summer. Complete spawning occurs by late summer-early autumn, and is followed by rapid phagocytosis of the residual material; oocyte proliferation occurs over the entire winter (Christiansen et al. 1974; Lasta and Calvo 1978; Narvarte and Kroeck 2000). Fecundity (estimated by stereometric techniques) ranges from 2 to 17 million eggs over a size-range of 35–90 mm shell height (Christiansen et al. 1973, 1974). Energy for gonadal development appears to come directly from feeding (de Vido de Mattio 1984; Orensanz 1986), not from reserves stored in the adductor muscle or other tissues.

Size of the larvae at settlement is 162–201 μm (Orensanz 1976). Settlement occurs primarily on shell-hash in San Matías Gulf, and on the macroalga *Ulva* in San José Gulf. Two peaks of settlement may occur in San Matías, matching the two spawning pulses. Only one major settlement season has been observed, however, in San José Gulf, where the late summer spawning never resulted in important settlement (Ruzzante and Zaiexo 1985; Ciocco 1985; Orensanz 1986). During the first 1.5 yr of life growth (shell height) is

quasi-linear (constant growth rate), with a seasonal component over imposed. Growth in weight, also seasonal, is related to the reproductive cycle (and thus to temperature) and food availability. Growth rate decelerates (the growth curve becomes asymptotic) past the second winter. Figure 26.3 shows growth pattern in size (height) of three cohorts in one site (top) and of a single cohort in three sites (bottom). Parameters of the von Bertalanffy model (H_{∞} and k) have been estimated for several data sets (Table 26.1).

Figure 26.2. *Aequipecten tehuelchus*. a: Geographic distribution (dotted area expanded in b). b: North Patagonic Gulfs; arrows indicate main scallop landing sites (1: San Antonio, 2: Puerto Lobos, 3: El Riacho, 4: Los Abanicos, 5: Tehuelche); dashed lines indicate main roads; shaded areas (NW, NE and S) indicate fishing grounds in San Matias Gulf. c: San José Gulf; shaded areas indicate scallops grounds; black triangles: landing sites (depth in m). (Modified from Orensanz 1986 and Ciocco et al. 1998).

Figure 26.3. *Aquipecten tehuelchus*. Cohort-specific growth patterns in San José Gulf, assessed with periodic samples. a: Growth of six year-classes during a 3-year study, San Román Ground; horizontal lines: average sizes at which the cohorts reach full detection by the quantitative sampling technique (H+), to size-dependent mortality (H*), and to commercial size (Hc). Symbols for the year-classes are (O) 1972, (□) 1973, (+) 1974, (X) 1975, (◊) 1976, (Δ) 1977. b: Growth of the 1980 year-class in three grounds (JP: Juan de la Piedra; T: Tehuelche; SR: San Román) (From Orensanz 1986 and Ciocco 1991).

Table 26.1

Aequipecten tehuelchus. Parameters estimated for the von Bertalanffy growth model by different authors.

Region	Ground	H_{∞} (mm)	K yr ⁻¹	t_0 (yr)	Source
San Matías Gulf	Bajo Oliveira	85.16	0.40	-0.88	Olivier and Capitoli 1980
San José Gulf	Gales	75.24	0.70	-0.03	Ciocco 1985
"	Logaritmo	82.12	0.57	-0.10	"
"	San Román	82.86	0.75	0.19	Orensanz 1986
"	San Román	77.17	0.98	-0.12	Ciocco 1991
"	J. de la Piedra	79.19	0.86	-0.07	"
"	Tehuelche	71.68	0.84	-0.09	"

Figure 26.4 shows growth in weight of different body parts, over two years (Nov. 1974–Nov. 1976) and for 3 year-classes (1973–1975), in San Román Ground (San José Gulf). Adductor muscle grew rapidly during the autumn, and the gonad during late-winter/early-spring of 1974, suggesting that energy from food was sequentially diverted to reserve storage (autumn) and gonadal maturation (spring). During 1976 (a year in which density was high) there was not a period of fast muscle growth. Other seasonal changes seemed to occur in phase (growth rates of the different body fractions were not negatively correlated). The weight of muscle and other meats drop synchronously with the gonad after spawning (de Vido de Mattio 1984; Orensanz 1986). This drop occurred for all year-classes and for all the spawning peaks detected, and is consistent with a rapid decline in content of glycogen (de Vido de Mattio 1984). Meats lose commercial value after spawning. Relative yield in muscle weight varies with season, area and density. In the San Roman ground it was 20% of total weight during the winter of 1975 (when density was low), but dropped to 15% one year later, after mean biomass increased to above 1 kg m⁻² (Fig. 26.4).

Diet consists mainly of benthic microscopic algae, probably resuspended by tide or wind generated near bottom currents or turbulence (Vernet 1977). Only on one occasion (January), during one year of monthly sampling, did planktonic algae (largely the dinoflagellate *Prorocentrum micans*) constitute the main component of the diet. This was reflected in an increase of 22:6 ω -3 fatty acid (a major component of dinoflagellate lipids) in the gonad and meats during that particular month (Pollero et al. 1979).

The Tehuelche scallop may do quick and brief swimming movements as escape responses to predators or other disturbances. Frequency of byssal attachment to the substrate vanishes gradually with age, but the capacity to form a byssus is not lost in the adults (Ciocco 1992a). Attachment rate of adult scallops (age 2 + and older) in the field increases with current velocity, from 65% at 4–5 m min⁻¹ to 90% at 7–8 m min⁻¹ (Ciocco et al. 1983).

Figure 26.4. *Aquipecten tehuelchus*. San Román Ground, San José Gulf. Growth of adductor muscle (a, c, e), gonad (b, d, f), meats (g) and shell (h) between November, 1974, and November, 1976. Year-classes: (o) 1973, (□) 1974, (+) 1975. Relative weights (c, d) are expressed as percentages of total weight. Horizontal dashed lines in a and e separate commercial standards for muscle size (large, medium, small). Shaded bands in a indicate summers (S) and winters (W). Shaded areas in e and horizontal bars in d indicate springs (SP). Horizontal bars in c indicate fishing seasons (From Orensanz et al. 1991).

26.2.2 Population Dynamics

The stock from San José Gulf (the only one on which studies of population dynamics have been conducted) is structured as a metapopulation whose component sub-populations ('grounds') are inter-connected by larval dispersal (Fig. 26.2c). Location of grounds has been consistent through time (some have been known for more than 30 years). In some cases this may reflect the presence of eddies (produced by wind or tides, and coastal accidents) that function as areas of larval retention. Each ground is exposed to a distinct regime of food availability, predation and disturbance. Inter-population gradients in growth rate correspond largely to gradients in nitrogen availability, primary production and carrying capacity (all decreasing from northwest to southeast; Orensanz 1986; Ciocco 1991, 1992c). Intra-population differences in individual growth rate have been attributed to density-dependence. Fluctuations in abundance in the different grounds are largely out of phase, although some degree of synchrony points to large-scale modulation of recruitment. Settlement, for example, was strong everywhere in 1975 and insignificant in all the grounds in 1976. Spatial distribution within the grounds is contiguous; most individual scallops experience high concentration in their neighbourhoods.

Stranding, induced by storms and strong winds, seems to be the main source of mortality (Orensanz 1986; Orensanz et al. 1991). Sporadically it can reach catastrophic proportions, wiping out entire grounds. Stranding mortality seems to increase with size, perhaps because byssal attachment gets weaker while epibiotic load increases the flow-induced forces encountered by the scallop. Pulses of mortality were observed following minima in condition index: late-winter/early spring (minima of food availability and temperature) and after spawning. Main predators include a starfish (*Cosmasterias lurida*), a volutid snail (*Odontocymbiola magellanica*), an octopus (*Enteroctopus megalocyathus*), and a ratfish (*Callorhynchus callorhynchus*) (Orensanz 1986, Di Giacomio et al. 1994; Ciocco and Orensanz 2001).

The San Roman Ground population (Fig. 26.2c) appears to be regulated by a combination of density-dependent growth and settlement, and size-dependent mortality (Orensanz 1986). Reproductive output was also depressed as a result of density-dependent effects. Natural mortality is very low within the size range [30–52 mm], and increases with size above 52–54 mm height. For that reason, mortality rate was higher in cohorts which grew faster: mean instantaneous per-capita mortality rate (above a mean size of 52 mm) was 1.98 yr⁻¹, 0.99 yr⁻¹ and 0.62 yr⁻¹ for the year classes 1973, 1974 and 1975 (respectively) which grew under increasingly high density conditions (Orensanz 1986). Ciocco (1996) reported significant geographic and temporal variation in "in situ" natural mortality, estimated from a combination of data on relative clucker abundance and mean clucker "life" (Tehuelche Ground: 0.21–1.56 yr⁻¹; San Román Ground: 0.27–1.22 yr⁻¹).

Average biomass and production are locally constrained by carrying capacity. In San Román, biomass reached an average of 1.3 kg m⁻² during peaks of abundance, and a maximum (for individual patches) of 1.5 kg m⁻². Compensatory effects became detectable above 1 kg m⁻². Age at recruitment (60 mm, legal size) ranged from 1.5 to 2.2 yr, depending upon density conditions. Production in the core bed of the San Román ground

was similar for two years (1975, 1976) that differed in average biomass, reflecting compensation. Annual production of meat was $382 \text{ g m}^{-2} \text{ yr}^{-1}$, very close to the $379 \text{ g m}^{-2} \text{ yr}^{-1}$ that Charpy-Roubaud et al. (1982) calculated that could be sustained by primary production. In an independent study conducted on the same ground a few years later, Ciocco (1991) estimated values remarkably similar: $359 \text{ g m}^{-2} \text{ yr}^{-1}$ and $368 \text{ g m}^{-2} \text{ yr}^{-1}$, respectively. Corresponding values estimated in the same study for the Tehuelche Ground were, as expected, lower (respectively $210 \text{ g m}^{-2} \text{ yr}^{-1}$ and $238 \text{ g m}^{-2} \text{ yr}^{-1}$).

Year-class strength and average biomass showed a quasi 5-year cycle over a 20-year period in San Román Ground (1969–1990) for which information is available (Orensanz 1986; Ciocco and Aloia 1991). The cycle was produced by five evenly spaced, exceptionally strong year classes (1970, 1975, 1980, 1984, 1987). Abundance of year classes varies among populations in the San José Gulf. While the San Román sub-population (on the north coast) was dominated by one strong year class, the Tehuelche sub-population (on the south coast) has shown, over the years, a multi-cohort composition. Because of this the Tehuelche area has been suggested as a reasonable location for a reproductive reserve (Orensanz et al. 1997).

26.2.3 Fisheries

26.2.3.1 The inshore dredge fishery of San Matías Gulf (Río Negro Province)

The main fishing areas of San Matías Gulf (Fig. 26.2b) are located on the northwest (Bajo Oliveira-El Sótano) and north-northeast (Orengo beach and surroundings). Most of the beds in these fishing grounds occur at depths greater than 20 m, and for that reason are largely inaccessible to commercial divers. Starting in 1995 sporadic harvests have been made by commercial divers near Puerto Lobos, on the S coast, and near El Fuerte (NW) of San Matías Gulf (Fig. 26.2b), at depths of 12–15 m. On that year 10 boats fished over 100 tons.

The dredge fishery for scallops, which is centred in San Antonio Oeste (Río Negro Province), boomed in 1969 due to favourable conditions in the international market. Boats that arrived in San Antonio from other areas of the country numbered 18 by 1972. Catch peaked in 1970 at 4,530 MT (Fig. 26.6a). Olivier and Capitoli (1980) reported a catch of 13,904 MT for the same year, but their data correspond to the unsorted catch; catch figures reported here correspond to scallops only. The CPUE dropped rapidly during the 1971 fishing season, following three years of intense harvesting.

The fleet was composed of stern-trawlers, 12–22 m long (Olivier et al. 1970). The Argentine scallop dredge (Fig. 26.5), developed in the thirties for mussel fishing, is built of iron pipe, 3 cm mesh chicken wire, and strips of spare tires; a smaller and lighter design was introduced during the 2000 fishing season (Morsan et al. 2000; Narvarte and Morsan 2000). The catch was not sorted on board during the 1968–1972 fishing period. The landed catch was composed of scallops (normally 30–40% of gross yield), other benthic invertebrates, and shell hash. Efficiency of the larger dredge has been estimated at 11–16% (Vacas et al. 1984) and 15–21% (Iribarne et al. 1991); it is completely unselective

Figure 26.5. Dredge design traditionally used in the Argentine Tehuelche scallop fishery (From Orensanz et al. 1991).

due to clogging of the bag. No studies on the selectivity of the new design were carried out yet. Since 1990, including the last 2000 season, the catch was sorted on board.

Studies were conducted for the first time during the summer of 1970 (Olivier et al. 1970), and were followed by surveys of the fishing grounds in 1971–1973 (Olivier 1972; Olivier et al. 1971, 1973, 1974; Olivier and Capitoli 1980). Management recommendations during the first period included selection of the catch onboard, a

minimum size (height) of 60 mm, and the closure of the fishery at the beginning of the spawning season (spring). The provincial fishery administration was, however, unable to enforce all of these measures. The fishery was closed at the end of the 1971 season, reopened briefly in 1972 (1,700 MT landed over three months), closed again, and reopened for one month in 1975. The remnants of the 1970 year-class (the last successful one) were wiped out by fishing and a storm (Orensanz et al. 1982). Afterwards, the fishery remained closed for six consecutive years. Its 'first pulse' was over.

Figure 26.6. *Aequipecten tehuelchus*. Landings by year. a: San Matías Gulf dredge fishery; b: San José Gulf diving fishery (modified from Ciocco et al. 1998).

The 1980 spawning season was followed by strong settlement over the traditional fishing grounds (NW of the gulf; Fig. 26.2b), and the 'second pulse' of the fishery started in 1982, with a small-scale experimental fishing program. A management program was implemented in 1983 that included regulation of fishing effort (fleet size). Catch information was improved by cross checking data from the fleet and the buyers. Landings rose to 2,336 MT in 1983 (Fig. 26.6a), about half the peak of the 'first pulse' (1970). New fishing beds were discovered in the N-NE part of the gulf (Fig. 26.2b), allowing rotation of areas in 1984. The traditional NW ground was closed, and the N-NE ground (populated by a mixture of year classes) opened. Effort regulations were relaxed in 1984, leading to a rapid increase of fleet size. Although both grounds were opened in 1985, total landings declined (Fig. 26.6a). The NW ground was depleted; no significant settlement occurred until 1999, almost 20 years later.

Management again became conservative starting in 1986, in the face of a new collapse of the fishery. Significant settlement in the N-NE area in 1986 supported the fishery through 1990, this becoming the third pulse of the fishery. Only 4–6 boats operated, and catches were comparatively small (Figure 26.6a). An area-rotation program was effectively implemented during those four years by the provincial fisheries administration to protect areas where juvenile scallops predominated (Vacas et al. 1984). Yet, after the pulse was over following the 1990 season, no signs of recovery were detected in the N-NE grounds until 2000.

Landings were insignificant during the 1990s (Figure 26.6a) due to poor recruitment. In 1991–1992 scallops were landed only as by-catch (Morsan and Narvarte 2000). In 1992 two trawlers fished in the NE area, and during 1993 and 1994 two diving teams fished in shallow waters at the NW sector (Ciocco et al. 1998). The fishery was completely closed from late 1994 to 1999, except for illegal diving operations in 1995. In October, 2000, the fishery administration opened the Bajo Oliveira bed (NW fishing ground) during a 45-day season and with a 350-ton quota; participants, only artisanal boats, included both dredgers (6 boats) and commercial divers (5 boats) (Morsan et al. 2000; Narvarte and Morsan 2000).

In summary, just a few year-classes (1970, 1980, 1986 and 1999) have supported the fishery over the last 30 years. The fisheries authority considers that the only conceivable strategy to manage this spasmodic stock is an opportunistic allocation of effort (in space and time), in order to maximise the yield of unpredictable settlement pulses, with specific measures based on pre-season surveys and yield-per-recruit analysis. Surveys may allow the forecast of recruitment pulses up to two years in advance, facilitating a better spatial allocation of effort.

26.2.3.2 The commercial diving fishery of San José Gulf (Chubut Province)

While the San Matías fishery boomed in 1968–1970, some sporadic dredging was also done in the San José Gulf. Good fishing grounds were located by 1970, but the Chubut Province fishing authority, having witnessed the collapse of the fishery in neighbouring San Matías Gulf (Rio Negro Province), banned the use of dredges. Preliminary diving operations started in 1970–1971, and by 1972 the first efficient boat

geared for commercial diving started to operate (Picallo 1979; Ciocco et al. 1998). Commercial diving is possible in this area because scallop beds are generally found at depths below 20 m.

The development of the fishery has been chronicled by Ciocco (1995b) and Ciocco et al. (1998); landings are summarised in Fig. 26.6b. Activity between 1971 and 1973 was incipient and irregular. The first commercial diving teams used inner engine boats, with 4–6 divers each. CPUE was high, in the order of 600 kg diver⁻¹ d⁻¹, and there were no regulations. The fishery was closed shortly in 1972–1973, and then in 1974–1975, in both cases as preventive measures while a management plan was put together. Surveys conducted in 1973/1975 showed high scallop abundance (Olivier et al. 1974; Picallo 1980).

The fishery was opened every year during the 20-year period 1975–1995, to commercial divers only. Initial regulations (Olivier et al. 1974) included: i) a closed season, ii) ad-hoc area closures for the protection of sub-legals, iii) a size limit (60 mm), iv) catch only by diving (ban on dredging), and v) quotas. These regulations have continued with little change. The 60 mm legal size, originally established to allow one spawning before harvest, turned out to be a reasonable choice for other reasons: (1) maximum biomass of a cohort is reached around the age of 1.5 yr, shortly before 50% of the individuals reach legal size, and (2) average adductor muscle weight entered the smallest marketable size (in the export market) about two weeks after scallops (on average) reached legal size (Orensanz 1986). Diving fishermen soon developed a search image for size, and selected large scallops for economic reasons, whether a minimum size was enforced or not. Given these conditions, and the fact that harvestable beds were usually dominated by one strong year class, growth overfishing was not a main management concern in this fishery. Divers selected beds with the highest densities (40–60 scallops m⁻²). Threshold density was around 20 scallops m⁻². Since growth and recruitment rates are thought to be density-dependent, it was claimed that the diving fishery had the potential for self regulation (Orensanz 1986).

The fishery consolidated between 1976 and 1985. Outboard motor boats (ca. 8-m long, with 35–110 HP motors) became the standard; the fleet consisted of 5–6 teams (one team per boat) fishing during each season. Effort concentrated on the S-SW of the gulf, and catch ranged from 100 to 500 MT yr⁻¹ (Fig. 26.6b). CPUE declined from 600–800 kg diver⁻¹ d⁻¹ between 1976 and 1980, to 300–400 kg diver⁻¹ d⁻¹ between 1981 and 1985. After 1981 fishing was affected by red tide events during the warm season. In 1986 the fleet operated mostly on the north coast, and to a lesser extent to the east of the Gulf. The number of boats grew to 12–30, while CPUE declined from ca. 600 kg diver⁻¹ d⁻¹ in 1986 to less than 150 kg diver⁻¹ d⁻¹ in 1995 (a historical minimum for this fishery); catch, which fluctuated between 370 and 850 MT yr⁻¹ during the period 1985–1994, dropped to 100 MT in 1995.

The 1995 fishing season was closed in advance due to an excess of sub-legal size scallops in the landings. Subsequently the fishery was closed for three years (1996–1998) due to low abundance (Ciocco et al. 1996, 1997). Several factors led to the collapse of the fishery in 1995: i) a domestic market developed for sub-legal size scallops, ii) the efficiency of the fishing units improved, iii) due to economic hardship in the country

divers fished at progressively lower density thresholds, and risked fishing deeper beds, iv) fishing effort increased in the absence of a limited-entry program, v) lack of monitoring and enforcement. Removal of previous reproductive refugia (low density and deep beds, sub-legal size scallops) probably led to poor settlement. The fishery was reopened partially in 1999 and normally in 2000 (both seasons with quota; around 100 MT fished in 1999 and 240 MT in 2000; Fig. 26.6b).

26.2.4 Aquaculture

26.2.4.1 *Spat collection*

Except for some trials in San José Gulf (Zaixso 1980; Zaixso and Spindola 1981; Zaixso and Toyos de Guerrero 1982), studies on spat collection in Argentina have been conducted mostly in San Matías Gulf (Río Negro Province; Fig. 26.2b), where experiments began in 1980. These were continued over twelve experimental seasons (1980–1985, 1989–1993 and 1996–1999), yielding results relevant for the development of culture techniques for *Aequipecten tehuelchus*. These are outlined below.

26.2.4.1.1 *Vertical distribution of settlement*

A significant correlation was observed between settlement on spat collectors and depth. Abundance of postlarvae per collector was highest (1973 'seed'/collector) in the collector closest to the bottom (1 m), and declined progressively towards the surface (Narvarte 1995) (Fig. 26.8). The settlement pattern observed in San José Gulf (Fig. 26.1) was less clear: in one experiment settlement was highest near the bottom, but in other occasions no correlation with depth was observed (Ciocco and Monsalve 1999a, b), or even the reverse pattern was observed (Ruzzante and Zaixso 1985).

26.2.4.1.2 *Temporal variation in settlement*

In San Matías Gulf the maximum intensity of larval settlement occurred in January–February in 9 out of 12 experimental seasons. In the other three seasons the number of settlers per collector reached its maximum after February (Orensanz et al. 1991, Narvarte 1995, 1998). Settlement on artificial substrates varied considerably, seasons with successful spat collection alternating with others in which it was virtually absent (Table 26.2).

26.2.4.1.3 *Type of collector*

Four types of collectors were tried in San Matías Gulf on longline system (Fig. 26.7): a) Japanese “ren”, b) branches of “jarilla” (*Larrea divaricata*, a shrub common in the region) packed in onion bags (6 mm mesh), c) Japanese Netlon collectors with an external bag (2 mm mesh), and d) onion bags packed into external bags with a finer mesh (2 mm). With the first type the average number of postlarvae collected varied between 1 and 33

Table 26.2

Aequipecten tehuelchus. Interannual variability of settlement on spat collectors, San Matías Gulf.

Study periods	Successful seasons	Seasons with no settlement
1980–1985 ^(a)	1980–1981; 1982–1983	1984–1985
1989–1993	1989–1990; 1991–1992	1990–1991; 1992–1993
1996–1999	1996–1997; 1998–1999	1997–1998; 1999–2000

(a) from Orensanz et al. (1991)

per 100 mm² (Orensanz et al. 1991). These values are hardly comparable with those obtained in nets. The number of settlers per Netlon collector was far higher than in the other two types of net-mesh collectors, although collectors with an external fine mesh gave yields adequate for a commercial operation (Narvarte 1998, 2001). Highest average number of juveniles per “jarilla” collector was 146.4 (SE = 45.7), while the average for Netlon collectors was 589.5 (SE = 86.8).

Figure 26.7. *Aequipecten tehuelchus*. Longline spat-collection system used at different sites in San Matías Gulf (schematic, collector types described in the text).

Figure 26.8. *Aequipecten tehuelchus*. Average number ($\pm$ SE) of postlarvae/collector obtained at different depths (expressed as distance from the bottom: I = 3 m, II = 2 m and III = 1 m) during the 1991–1992 season.

26.2.4.1.4 Location

Experiences in San Matías Gulf were conducted at three different locations (Narvarte 2001): Playa Orenge (NE), El Sótano (NW) and El Fuerte (NW) (Fig. 26.2b). The number of settlers obtained in El Sótano was significantly higher than values for the other sites (Table 26.3). Three sets of lines were placed at each of the sites with the purpose of comparing spat collection at a smaller spatial scale (300 m on average). At this scale no significant differences were observed. Ciocco and Monsalve (1999a, b), in experiments conducted to assess larval availability in San José Gulf, also observed differences between sites. Spat density in Tehuelche (S) and San Román (N) was higher than in Mendioroz (W), although Fracasso (SE) was the location with the highest observed levels (Table 26.3).

26.2.4.1.5 Influence of depth, type of collector and location on the average size of the 'seed'

Significant differences in average seed size were observed between depths, collector types, and collection locations (Narvarte 2001). Differences associated with the first two factors may be related to the differences in the loss-rate of attached seed, while differences between sites may be attributable to the settlement of different larval cohorts.

Table 26.3

Aequipecten tehuelchus. Number of juveniles per spat collector in different locations of the Argentine coast, 1996 and 1999.

Region	Site	Mean	SD
San Matías Gulf	El Sótano	590	86.8
	El Fuerte	174.9	82.84
	Orengo	246	74.4
San José Gulf	Tehuelche	134	40.9
	Fracasso	786	260.92
	Mendioroz	14	2.83
	San Román	107.5	0.71

26.2.4.2 Growth in suspended structures of spat obtained from collectors

Three experiments were conducted in the region between 1982 and 1990. Zaixso (1982) utilised lanterns for intermediate culture (up to 30 mm shell height), and devices with rigid mesh and individual pockets for larger individuals, in two locations of San José Gulf. Experiments conducted in San Matías Gulf utilised plastic boxes suspended in mid-water. In the first (1985), a rigid plastic mesh enclosed the juveniles, which were spread over hard-plastic trays. An average size of 57 mm (shell height) was reached after 24 months (Orensanz et al. 1991). A second experiment employed the same plastic box, but the net enclosing the scallops was lighter and flexible. The same size was reached after only 13 months (Narvarte 1995).

Starting in 1996 the growth of juveniles was studied in three different suspended structures, all of them widely used in Japan: 1) cage (identical to the one used before), built with five rigid plastic trays, and covered inside with onion bag, 2) Japanese lantern, with 10 levels and a mesh size (6 mm) similar to that utilised in the cage, and 3) ear suspended (starting with scallops 37-mm high) (Narvarte 1999). The three structures were suspended vertically from a longline. The size of the juveniles was followed over 13 months (Fig. 26.9). The ear-suspension method was abandoned after three months due to the large volume of epibionts that attached to the valves (Fig. 26.10). In the case of the other two structures (cage and lantern), the season of fast growth went from April to December, when spawning takes place (Narvarte and Kroeck 2000). Growth rate slowed down afterwards (Fig. 26.9).

The von Bertalanffy growth model was fitted to data from the three experiments, and the different curves were compared using maximum likelihood methods. Commercial size was reached fastest in the lanterns, which were also easier to handle on board of small boats (Narvarte 1999). The relative mass of epibionts was comparable in the two structures and the difference between these and ear-hanging was significant (Fig. 26.10).

Figure 26.9. *Aequipecten tehuelchus*. Growth of juveniles kept in cages and lanterns, San Matías Gulf.

Figure 26.10. *Aequipecten tehuelchus*. Yield (weight of the final product, as a percentage of total weight with epibionts included) obtained from juveniles grown in cages, lanterns, and ear-hanging.

26.2.4.3 Larval culture in the laboratory

Experiments designed to optimise conditions for fertilisation and larval development included: a) fertilisation utilising different concentrations of sperm, b) incubation of embryos at different densities, c) feeding of the larvae with different algal diets, and d) settlement of the larvae on different substrates.

Spawning was induced by thermal stimulation. The number of D-veliger larvae obtained with 30–50 spermatozooids per egg was significantly higher to that obtained with 10 spermatozooids per egg. The 10:1 ratio, frequently used in aquaculture operations, yielded relatively few larvae.

Fertilised eggs were placed in glass containers at three different densities: 350, 700 and 1050 eggs mm⁻². No difference was found in the number of larvae obtained in these treatments, indicating that those are below the level at which density-dependence begins to operate, and that the highest density assayed could be used for incubation (Narvarte and Pascual, unpubl.).

Larval growth was assessed under three diets: a) *Isochrysis galbana* + *Chaetoceros calcitrans*, b) *Pavlova lutheri* + *C. calcitrans*, and c) *I. galbana* + *P. lutheri* + *C. calcitrans* (Narvarte and Pascual 2000). The diets containing *P. lutheri* yielded a significantly higher growth rate. Final average larval size varied among diets (Narvarte and Pascual 2000):

- a) Iso + Ch: 161.77 µm (SE = 19.07)
- b) Pav + Ch: 175.59 µm (SE = 21.66)
- c) Iso + Pav + Ch: 200.48 µm (SE = 21.13)

The effect on settlement of adult shells (natural settlement substrate in San Matías Gulf) and young thalli of *Ulva lactuca* (natural settlement substrate in San José Gulf; Ciocco 1985) was investigated by observing the density (number of postlarvae per cm² of substrate) on experimental collectors. There was no difference between the two treatments; density of settlers was correlated with substrate surface ($r = 0.74$; Narvarte and Pascual, unpubl.).

26.2.4.4 Prospects and problems

Given that successful spat collection is obtained (on average) every two years, and considering that settlement in the natural environment is highly variable (episodes spaced 5–10 years in San Matías Gulf), the restocking of fishing grounds with seed from collectors is presently under consideration. However, a retrospective evaluation of research conducted over more than a decade highlights several problems that require further attention:

- i. Year-to-year variation in spat collection.
- ii. High cost of structures used for aquaculture, so that they cannot be left in exposed or unprotected locations.

The development of technology for the mass production of hatchery larvae will be conditioned by the knowledge obtained from the experiments under way. The following problems require further scrutiny:

- i. In the case of hatchery work, the partial spawnings of the Tehuelche scallop provide small quantities of viable eggs at a time. This makes it necessary to stimulate a large number of spawners.
- ii. High mortality (up to 90%) during the first week of larval culture in tanks.

26.3 THE PATAGONIAN SCALLOP, *Zygochlamys patagonica*

26.3.1 Biology and Ecology

Zygochlamys patagonica (Fig. 26.1) is a species typical of the Magellanic Biogeographic Province (Waloszek 1984). It is distributed around southern South America, reaching 42° SL on the Pacific and 36° 15' SL on the Atlantic, between 40 to 200 m depth (Lasta and Zampatti 1981; Waloszek and Waloszek 1986; Defeo and Brazeiro 1994; Fig. 26.11) although some individuals have been reported from down to 960 m deep (Waloszek 1991). While grounds on the Pacific side occur in relatively shallow waters (Andrade et al. 1991), Atlantic grounds are oceanic, the most important beds being located along the 100-m isobath.

The spatial distribution and biological characteristics of scallops are probably related to hydrographic regimes. The continental shelf of the southwestern Atlantic is dominated by: (1) subantarctic waters, mainly the upper layer of the Malvinas Current, that flow through the west of Burdwood Bank (Guerrero et al. 1996), and (2) continental runoff that enters the shelf through the Magellan Strait (Krepper 1977; Bianchi et al. 1982) and the Tierra del Fuego Channels (Lusquiños and Valdes 1971). The Malvinas Current flows towards the north along the continental slope, transporting subantarctic waters characterised by high salinity and low temperature (Piola and Gordon 1989), converges between 35° and 40° SL with the Brazil Current, then flows poleward, generating a strong frontal zone between Subantarctic and Subtropical waters (Reid et al. 1977; Legeckis and Gordon 1982; Gordon and Green Grove 1986). The differential heating between shelf and slope regimes during the warm seasons develops a shelf-break front observed as a horizontal temperature gradient over the 90–100m isobath (Martos and Piccolo 1988; Baldoni 1993). This highly productive front (Brandhorst and Castello 1971; Carreto et al. 1981, 1995; Podestá and Esaías 1988, Negri 1993; Bertolotti et al. 1996) may be the factor that influences the area of distribution of beds located at these depths (Fig. 26.12). Tres Puntas and Sea Bay beds (Fig. 26.12) are influenced by a low salinity coastal system of continental origin, mainly via Magellan Strait and Tierra del Fuego Channels runoff (Brandhorst and Castello 1971; Lusquiños and Valdes 1971; Krepper and Rivas 1979; Guerrero and Piola 1997). The Tres Puntas Bed is associated with the coastal regime, characterised by water mixed due to tidal effect, with high nutrient concentration throughout the year and high chlorophyll concentration (Bertolotti et al. 1996). The Sea Bay Bed is associated with the intermediate shelf regime, characterised by lower productivity (Carreto and Benavides 1990; Carreto et al. 1995) due to strong seasonal

Figure 26.11. *Zygochlamys patagonica*. Geographic distribution. Dark areas represent main fishing scallop grounds in Uruguay, Argentina and Chile.

variation in the vertical structure of the water column, with an homogeneous layer in winter and a two-layer structure during warm months resulting in a strong thermocline (Krepper 1977; Bianchi et al. 1982). It is likely that currents associated with these frontal systems increase the food supply and/or helps retain drifting larvae (Natural Resources Consultants 1995).

Larval interconnection between the beds was inferred from current meter information, through simulation of the progressive trajectory of an ideal particle during a 30-day period, corresponding to the presumed duration of the pelagic larval stage (López 1998, Lasta et al. 1998). Mean vector speed, at 17 and 67 m depth was estimated at 5 cm s^{-1} with N-NE direction. Under these conditions, beds influenced by the shelf-break front and separated by distances fewer than 90 km could be interconnected by larval drift, assuming that larvae behave as passive particles. This pattern is more unrealistic in beds subject to coastal and intermediate shelf regimes, due to horizontal stratification.

Figure 26.12. *Zygochlamys patagonica*. General location of scallop beds. CFZ: Common Fishing Zone (Uruguay-Argentina), NMU and SMU: Northern and Southern Management Units.

Studies on the benthic assemblages of Patagonian scallop beds were conducted in 1995, before they were disturbed by fishing operations. A total of 82 invertebrate taxa, representing 10 phyla, was recorded (Bremec and Lasta 1997, 1998). Although dominance (in terms of weight) in the epibenthos varied much among beds, its components characterise a distinctive assemblage quantitatively dominated by *Zygochlamys patagonica* over the investigated latitudinal range. The undisturbed beds were distributed along the shelf-break front (39°–43°S), and in regions under the influence of low salinity coastal regimes (44°–47°S). *Z. patagonica* was the dominant species (21%–58% of total biomass), followed by other suspension feeders (Porifera), predators (Cnidaria, Asteroidea, Gastropoda, Crustacea) and grazers-detritivores (Echinoidea, Ophiuroidea). The Patagonic scallop, the ophiuroids *Ophiuroglypha lymanii*, *Ophiactis asperula* and *Ophiacanta vivipara*, the echinoids *Austrocidaris canaliculata* and *Sterechinus agassizi*, and the anemone *Actinostola crassicornis* contribute most of the between-sites similarity (57.7) (Bremec and Lasta 2002). The most frequent epibionts are *Iophon* sp. (Porifera), *Alcyonium* sp. (Coelenterata), *Serpula narconensis* and *Idanthyrsus armatus* (Polychaeta), *Magellania venosa* and *Terebratella dorsata* (Brachiopoda), *Hiattella solida* and *Calyptraea pileolus* (Mollusca), and *Ornatoscalpellum* sp. (Crustacea).

Sexes are separate. Sequential protandric hermaphroditism was suggested based on observations of the size frequency distribution (SFD) by sexes (Orensanz et al. 1991), and on histological indication of a possible sexual inversion (Calvo et al. 1998). However, continuous studies conducted in the Reclutas Bed do not indicate significant differences in the SFDs of the sexes (sexing from frodis preparations; Bigatti and Bonard 2000). Only one hermaphrodite (61 mm shell height) was found among approximately 400 individuals histologically examined (E. Christiansen, pers. comm.).

Sexual maturity is reached at ca. 45 mm (shell height), which correspond to an approximate age of 2 years (Waloszek and Waloszek 1986), although a mature female 15 mm high was found (Calvo et al. 1998). There is no external dimorphism. Spawning takes place mainly during spring, although a second pulse has been reported in late summer to early autumn (Waloszek and Waloszek 1986).

Field observations showed that living scallops (mean shell height 57.2 mm) constitute the main settlement substrate (98.8% of total records) for juveniles between 3–30 mm shell height. Settlement experiments confirmed that individuals between 3–13 mm shell height are always attached (Bogazzi and Lasta 2000).

Size composition shows that recruitment varies between beds (Lasta and Bremec 1998). In 1995 unimodal size distributions characterised the Valdés and Sea Bay Beds, mainly composed by adults. However, size composition in the Reclutas Bed was consistent with intense recruitment during 1994, probably from early spring spawning but also showing a summer-autumn 1995 pulse. Successful recruitment has been registered in Reclutas Bed over the years (hence its name). Cohorts identified by tracking SFDs over time corresponded to the 1992, 1994, and 1995 cohorts; a weaker one settled in 1996–97 (Valero 1999). Recently (cruises from 2000), massive recruitment was observed in all beds (Lasta 2000). The assessment of biomass between 1995 and 2000 does not indicate a

shortage of spawning stock. Large-scale hydrographic or ecological phenomena may govern the recruitment pattern observed (Lasta et al. 2001b).

Gut contents (35–50 mm-high scallops) are presently being studied on the basis of a study spanning one year cycle (Schejter, unpubl.). Preliminary results from spring 1996 in Reclutas Bed showed 60% of diatoms (mainly *Paralia sulcata*, *Nitzschia coarctata* and *Thalassiosira* spp.) and 20% of dinoflagellates (*Dinophysis mawsonii* and *D. rotundata*), plus prasinophytes, tintinids, foraminifers, silicoflagellates, and rests of sponges and arthropods (Schejter et al. 2000).

Soft tissues collected at Valdés Bed ($n = 50$; size range 30–78 mm) were not parasitised by metazoans (Cremonte 1999).

Analyses of heavy metals (Zn, Cu, total Hg and Cd) concentrations did not indicate accumulation in any tissue (muscle, mantle, viscera and gills). The lowest concentration of the four metals was found in muscle (Gerpe et al. 1995). Paralytic shellfish poisoning (PSP) was never detected through the control of meats (adductor muscle) landed by the commercial fishery (Sancho, pers. comm.). Separate analyses showed positive values of PSP in rests of viscera adhered to muscles from Tres Puntas Bed (Glaciár Pesquera, S.A., pers. comm.).

Enzymatic activity and reduced viscosity in adductor muscles are reduced by 35–40% after freezing at 2–4°C, mainly during the first two days (Paredi and Crupkin 2000).

26.3.2 Population Dynamics and Stock Assessment

Bimodal SFDs of the first annual ring (shell and ligament) has been interpreted as reflecting the two spawning peaks mentioned earlier. The first ring is assumed to be laid at a variable age, ranging from 0.5 to 1.5 years (Waloszek and Waloszek 1986). Size at settlement (inferred from the change in sculpture in the transition from prodissoconch to dissoconch in shells of adult individuals) is around 0.2 mm shell height (Waloszek 1984, Fig. 26.13). Individual growth in the Argentine Shelf was estimated by analysis of annual rings on the left valves and ligament by Waloszek (1979, 1991) and Waloszek and Waloszek (1986). These studies assumed that annual rings are formed during the winter, and that they are not related to spawning (Waloszek 1991). Recorded maximum size is around 90 mm shell height, and recorded maximum age is 10 years (few individuals are older than 8 years or higher than 80 mm). The von Bertalanffy growth model was fitted to size-at-age data by Waloszek and Waloszek (1986), Orensanz et al. (1991) and Valero (unpubl.). Estimated values of asymptotic height are in the range 53–79 mm, and estimated k in the range 0.35–0.67 yr⁻¹ (Fig. 26.13a). There is a significant decrease in asymptotic height as latitude increases (Fig. 26.13b). Legal commercial size (55 mm, Figure 26.13a) is reached at ages varying from 3 to 5 years over much of the latitudinal range, but in some areas the scallops hardly reach legal size.

Lowest and highest values of muscle condition index were observed in September and May, respectively, whereas the index of gonad condition was lowest during March–April and highest during August–September in samples taken between 1995–1998 from the Reclutas Bed (Lasta and Bremec 1999; Lasta et al. 2001b).

Figure 26.13. *Zygochlamys patagonica*. a: Von Bertalanffy growth curves fitted to size-at-age data from Waloszek and Waloszek (1986) and Valero (unpubl.). Solid horizontal line represents minimum commercial size (55 mm). b: estimated asymptotic shell height plotted against latitude. Dashed lines represent the range of estimates.

Total mortality rate estimated from SFDs (Reclutas Bed, 1995–1998) was 1.039 yr^{-1} (Lasta et al. 2001b).

Data obtained from 1995 to 1998 in Reclutas Bed show that the annual P/B ratio of the population was 0.679 yr^{-1} , corresponding to an annual total production of $45.5 \text{ g SFWM m}^{-2} \text{ yr}^{-1}$ ($= 4.02 \text{ g C}_{\text{org}} \text{ m}^{-2} \text{ yr}^{-1}$) (Lasta et al. 2001b). Muscle, soft tissue and gonad contributed 37.3%, 56.2% and 6.5% to total production, respectively. The major reason for this high P/B ratio is the low mean body mass in this population over the period of investigation. Estimates of productivity of the epifaunal community conducted in Reclutas Bed, based on fewer samples and on a P/B ratio derived from an empirical relation, resulted in lower production figures (Bremec et al. 2000). However, *Z. patagonica* dominated the epibenthic community in 1995, contributing 26% of the community biomass (3.15 g C m^{-2}) and 31% of community production. In 1998, community biomass (5.06 g C m^{-2}) as well as production were higher, and the share of *Z. patagonica* rose to 62% in both cases. A conspicuous decrease in biomass and annual production between 1995 and 1998, observed mostly among sessile taxa (Porifera and Cnidaria), contributed to reduce their share in biomass from 30% to 7%, and their share in production from 14% to 2%.

Table 26.4

Zygochlamys patagonica. Dimensions of beds (km²), sample size (N), total and commercial scallop relative density (Tsd, Csd, expressed in tons km⁻²) from evaluation cruises conducted during 2000. (*): Swept area method. CV = Coefficient of variation.

Bed	Area (km ²)	N	Tsd (t km ⁻²)	CV (%)	Csd (t km ⁻²)	CV (%)

Between 1995 and 1997 the stock was assessed using an index of abundance (CPUE, expressed as kg of commercial scallops/towing time) obtained from data recorded by the commercial fleet. Research cruises were started by Argentina's Institute for Fisheries Research and Development (INIDEP) in 1998 with the purpose of assessing absolute biomass in two management units (North and South). Sampling stations are spaced regularly at 5–6 nm intervals. The distribution of sampling stations is planned to cover the areas exploited since the beginning of the fishery. A non-selective 2.5-m wide dredge (efficiency 16–21%, Iribarne et al. 1991) is used; standard towing time and speed are 10 minutes and 3 knots, respectively. SCANMAR equipment is used to control the performance of the dredge over the bottom. Total catch is weighted and sub-samples are taken to estimate the percentage of commercial-size scallops, and to obtain SFDs. Geostatistical methods were recently introduced to estimate total and commercial abundance of scallops (Table 26.4) and to investigate changes in spatial distribution (Lasta and Hernández 1999; Lasta et al. 2001a).

26.3.3 The Fishery

26.3.3.1 Exploratory surveys and experimental fishing programs

The first commercial fishing operations were conducted in 1989 by the F/V "Sea Bay Alpha", a 64 m-long factory vessel. Although originally planned to extend for one year, the project was suspended after 24 days due to legal litigation. Most of the catch came from the Sea Bay Bed area. The muscle obtained was small in size (200 units per pound), but it was concluded that catch and muscle production were economically viable if the appropriate technologies were developed (Lasta 1992).

In 1991 an exploratory fishing trip off the coast of Uruguay was conducted by an Uruguayan company to locate scallop resources. The objectives were to test catch gear, to determine appropriate methods to harvest and handle the catch at sea, to develop a methodology for processing and packaging, and to collect data to assess the status of the stocks (DuPaul and Smolowitz 1994). An exploratory survey designed to assess the spatial distribution and composition of scallop stocks off Uruguay was conducted in the course of 17 trips during 1993 and 1994 (196 effective fishing day) by the F/V "Erin Bruce", a 56 m-long factory vessel (Defeo and Brazeiro 1994; Riestra and Barea 2000). The size of the muscles was small and the beds located were not extended; 772 MT of meats were landed (Riestra and Barea 2000). Vessel activity was suspended until January 1995.

Based on scattered data from exploratory and experimental fishing surveys (FRV "Prof. Siedlecki"/1973, Orensanz et al. 1991; FRV "Walther Herwig"/1978–79, Waloszek and Waloszek 1986; FRV "Walther Herwig"/1978–79 and FRV "Shinkai Maru"/1978, Lasta and Zampatti 1981, and FV "Sea Bay Alpha"/ 1989, Lasta 1992), a joint state-industry program was conducted in 1995 with the F/V "Erin Bruce" (which had been operating before off Uruguay) to evaluate the status of the resource across the Argentine Shelf. Data were collected by onboard observers in the course of 15 trips (Table 26.6). Results confirmed that the Patagonian scallop has a wide geographical distribution, with dense grounds between 50 and 130 m depth from 38° to 48° S (Lasta and Bremec 1998).

The F/V "Erin Bruce" was equipped with non-selective bottom otter trawls directly attached to the doors (otter board) (Lasta and Bremec 1997), 13 m in total length, a mesh size of 4 inches, and head and foot rope 15 m long. Estimated gear efficiency was 21–31% (Lasta and Iribarne 1997). The catch, composed of scallops, other benthic invertebrates and shell hash (Bremec and Lasta 1997), was mechanically processed onboard. By-catch and non-commercial size scallops were separated by drums and discarded, while commercial size scallops were processed as follows: (1) Steaming to open and separate soft tissue from the valves, (2) peeling to remove soft tissues and obtain muscles, (3) mechanical and/or manual control, and (4) freezing of the adductor muscle (IQF), grading in plates, and packing (Ciocco et al. 1998).

26.3.3.2 Management

A management plan was first outlined by INIDEP scientists following the experimental fishery of 1995, when basic information was collected (Lasta and Bremec 1997). The plan was conceived to incorporate adaptive criteria. The Argentine fisheries authority gave permits to two companies, each with 2 factory vessels, to start fishing commercially in 1996. Minimum legal size was set at 55 mm (total height), corresponding to an age of 3–4 years. No fishing season was imposed. Quotas were allocated to the fishing companies, even in the absence of strong information on stock size. A harvest rate of 40% of legal size biomass, and maximum meat counts (118 muscles pound⁻¹), were initially introduced, but subsequently suspended. Reproductive closures were demarcated within each bed. Fishing was also banned in areas selected to conduct research (Reclutas Bed, Fig. 26.12, Lasta and Bremec 1997). The companies

were required to provide detailed fishing logs; these recorded fishing effort, positions, total catch, muscle yield, trawling time, etc.

Following consultation between the fishing authority, the industry and the scientists, the plan took final shape in 1999, structured for 4 year plus 1.

Two "Management Units" (MUs) were defined: "North", between 36° 45' and 39° 30' SL (within the Common Fishing Zone-CFZ- shared by Uruguay and Argentina), and "South", between 41° and 43° 30' SL. The North MU (including the MDQ and Reclutas beds) has an extension of 13,181 km², and the South MU (including the San Blas, SAO, SWSAO, Valdés, TangoB and SW-TangoB beds) is 25,858 km² (Fig. 26.12).

During 1999, a Uruguayan factory vessel (F/V "Holberg", 50 m long, see Riestra and Barea 2000; Riestra 2000) began operating at the CFZ (Fig. 26.12), in the Argentine sector. A quota by country criteria was recently agreed upon.

26.3.3.3 Development of the fishery

Information on fleet activity from the start of the fishery is summarised in Table 26.6 (see also Lasta and Bremec 1999). Fishing time was relatively constant over the years (Table 26.3). Although swept area and number of tows increased after 1995, fishing pulses occurred on different areas (Fig. 26.14, Table 26.6). One of the vessels (F/V "Atlantic Surf 2", Table 26.5) left the fishery in October 1997; this was reflected in a reduction of the landings in 1998 (Table 26.6). However, muscle production rose that year due to increased activity in the South MU, improving factory efficiency (Table 26.3), and enhanced ability of the skipper to detect the densest patches. Differences in landed muscle and daily muscle production between 1997 and 1999 (two years comparable in swept area and total number of tows) were due to improved processing efficiency (Table 26.6 and Fig. 26.15c).

Towing time increased from the beginning of the program (1995) through 1999 (Fig. 26.15a), and scallop CPUE show progressive depletion (Fig. 26.15b). After five years the fleet has trawled all over the shelf, following a rotating pattern and shifting the allocation of fishing effort (Fig. 26.16). This pattern follows from skipper decisions, based on prior knowledge as well as information gathered while fishing.

The ratio between landed muscle and commercial scallop processed (without epibionts), or "muscle yield" (MY) is used as an index of performance. MY was never higher than 20%. Performance has increased progressively (Table 26.3) as a result of improved technology on board. These results were corroborated by observers. An increasing trend in muscle production per fishing day is, thus, a result of increased efficiency at the factory as well as improved knowledge to locate and harvest dense patches. Epibionts make up ca. 7% of total scallop weight.

The development of this fishery was conditioned by two facts: the stocks are far from fishing harbours, and the size of the muscles is relatively small, rendering hand-processing impractical. The only option was mechanical processing on factory vessels. This led to the implementation of the current strategy. It is illustrative to notice that the Patagonian scallop fishery (including Uruguay) has involved five of the few scallop factory vessels built around the world (Table 26.5).

Figure 26.14. *Zygochlamys patagonica*. Activity of the fleet during 1996–1999. Each point represents approximately four tows.

Figure 26.15. *Zygochlamys patagonica*. A: Median towing time per year (in minutes) for all vessels. B: Total CPUE (Catch-per-unit-effort, as kg per towing hour). C: CPUE, commercial size catch only (total height >55 mm), number above box indicates weight of landed muscles, in tons. SMU and NMU: Southern and Northern Management Units.

Table 26.5

Scallop factory vessels built around the world, and their current status.

Year	Factory vessel	Country of origin	Presently operating in
1986	Holberg	Norway	Uruguay
	Sea bay Alpha	Norway	Inactive
1987	Atlantic Surf 2 ⁽¹⁾	Norway	Russia
1988	Scalloper	Russia	Russia
	NN	USA	Never active
	NN	Norway	?
1990	Arctic Rose	USA	Never active
1993	Erin Bruce	USA	Argentina
1994	Alexygutnetsous	Russia	Russia
1996	Atlantic Surf 1	Canada	Argentina
	Mr. Big	USA	Argentina

⁽¹⁾ Active in Argentina between 1996–1997.

Vessels in the fleet that presently operates in Argentine waters have features similar to the F/V “Erin Bruce” (described above; see also Lasta and Bremec 1998). Average sailing speed is 9–10 knots and average towing speed is 4 knots. Bottom otter trawl was established as the regular fishing gear. The New Bedford dredge (4.5 m wide) was used for a short time (1996–1997) in south most beds. Trawl nets are operated with booms (“tangones”); the fishing activity goes on 24 hours a day. Depending on speed and other technical characteristics, the vessels can make 40–60 tows d⁻¹ net⁻¹. The storage-room has a capacity up to 210 MT, which, together with storage capacity for fresh water (used in steam production) and fuel, limits the duration of the fishing trips to 20–40 days. The main landing harbours are Mar del Plata and Quequén, and occasionally Ushuaia and Puerto Madryn (Table 26.6).

Besides the industrial fishery, a small artisanal fleet lands small commercial catches in San Jorge Gulf. The whole meats are sold to local consumers.

26.3.3.4 Observers program

The management plan requires the companies to pay technical observers onboard scallopers on at least 50% of the trips to collect information. Vessel activity (position, towing speed and time), data on catches (total and commercial scallop catch, size frequency distribution total scallop), and factory process (estimated losses in the steam and peeling processes) are obtained by observers. Relative to community composition and gear disturbance, a daily catch monitoring sampling records abundance, biomass and minimum and maximum sizes of the main associated invertebrate species.

Figure 26.16. *Zygochlamys patagonica*. F/V "Atlantic Surf 1", activity between 1996 and 1999. Each point represents approximately four tows.

Processing onboard problems are frequently detected and tested by observers, mainly through evaluation of drum losses, steaming and peeling. Results are used for back-calculation to control catches from the amounts of muscle landed.

26.3.3.5 Ecological effects of fishing

The scallop community is affected by fishing operations (including both bottom trawling and onboard factory work) through: (1) sediment removal, (2) habitat modification, (3) damage to benthic organisms, (4) removal of target species and by-catch, (5) discards of scallops <55 mm (minimum legal size), (6) discards of shell and viscera, and (7) discards of non-target invertebrates. Invertebrates caught as by-catch (including mobile species and scallop epibionts) are discarded at sea after sorting in the factory, where they are injured or killed.

Table 26.6

Zygochlamys patagonica. Characteristics of the Argentine fishery, 1995–1999. Total time of each trip detailed as: fishing, sailing and searching time. SMU: Southern Management Unit, NMU: Northern Management Unit.

¹percentage of total time at the sea

²SD = Standard deviation

To test community responses to different levels of fishing effort, a depletion experiment was conducted in 1995 (undisturbed condition) in an extensive portion of Valdés Bed (Lasta and Iribarne 1997). The area swept amounted to 2.2 times the size of the experimental plot (which was not fished afterwards) and 1.15 times the size of the rest of the bed (which was subsequently opened to the fishery); both sectors were sampled again in 1997 (Bremec and Lasta 1998, 1999). Main effects on the fauna were damage of non-target invertebrates (short-term response), reduced of biomass of sessile filter-feeders like sponges and coelenterates (long-term response), and increment in the amount of empty shells on the bottom (a result of on-board processing). Scallops survive at least one removal from the bottom (Lasta and Bremec, unpubl.). Samples taken two years after depletion showed a higher relative biomass of scallops (60% of the total catch) than places with lower but persistent fishing effort (40% of total catch).

26.3.3.6 Marketing

Fishing production (adductor muscles only) is frozen both in block and IQF and exported to U.S.A, Canada and the European Union (EU). Exports through one company (Glaciar Pesquera S.A. pers. comm.) were destined as follows: 61% to the EU, 28% to Canada, and 10% to the USA, and the rest to the domestic market of Argentina. Although technology to produce scallop hamburgers (under various commercial names) was developed, this product found no significant acceptance in the market. Average calibre is 160 to 220 muscles per kg. Current (2000) value of the product is U\$S 7.1 kg⁻¹ (Fob) in Buenos Aires (Argentina), although prices fluctuate due to high supplies of scallops produced in China through aquaculture (Glaciar Pesquera, S.A., pers. comm.).

ACKNOWLEDGMENTS

Juan Valero was supported by scholarships from the Fulbright Program and the University of Washington. Maite Narvarte acknowledges Sandro Acosta and Natalia Saiz for assistance in sampling work, to Marcela Pascual, Eduardo Zampatti, Myriam Elvira and Ignacio Agulleiro for hatchery work and Enrique Morsan and Raúl González for their comments on individual growth in culture experiences. Norberto de Garín assisted in the preparation of some *A. tehuelchus* figures.

Chapter 27

Scallop Fishery and Aquaculture in Chile

Elisabeth von Brand, German E. Merino, Alejandro Abarca
and Wolfgang Stotz

27.1 INTRODUCTION

The total Chilean scallop production has reached the third place worldwide in 1997, and has maintained this position since (Table 27.1).

Three scallop species are of commercial interest in Chile: *Argopecten purpuratus* (Lamarck, 1819), *Zygochlamys patagonica* (King & Broderip, 1831) and *Chlamys vitrea* (King & Broderip, 1831). A fourth species, *Chlamys amandi* is also mentioned, but doubts exist if this is a true species or represents populations of *Z. patagonica*. *A. purpuratus* has a higher commercial value and it is the only scallop being intensively cultivated in bays located in Northern Chile. *Z. patagonica* and *C. vitrea*, are only fished from natural populations in Southern Chile.

This chapter includes a description of the scallop species in Chile with commercial value, development and collapse of the fisheries, and as a result the start of scallop aquaculture, with a brief history of its development, its production methods, and an example of recovery of an overfished bed.

27.2 SPECIES DESCRIPTION

For a better understanding of the scallop distribution in Chile, we have to explain briefly that Chile is divided into 12 regions from north to south, and a metropolitan area, located between the regions V and VI, which is the only one without a coast (Fig. 27.1).

While three scallop species are exploited in Chile: *Argopecten purpuratus*, *Zygochlamys patagonica* and *Chlamys vitrea*, official governmental sources only distinguish two resources, the “Northern scallop” (*Argopecten purpuratus*), and the “Southern scallop” (*Z. patagonica* and *C. vitrea*) (Sernapesca 1999). In the latter case, this “Southern scallop”, as described in the fishing statistics, is mainly *C. vitrea*, because for many years the minimum size of capture for the Southern scallop was set at 75 mm, which is a size *Z. patagonica* almost never reaches. Just recently the minimum size of capture for *Z. patagonica* was set at 55 mm, but still both species are not separated in the statistics, thus the values represent the sum of the landings of both species. While *A. purpuratus* is only cultivated in the northern part of the country in Regions I – IV (Fig. 27.1), the two latter species are fished exclusively in the far south (Region XII). A fourth species, *Chlamys amandi*, is mentioned for regions X and XI, but doubts exist if it is a true species. Nevertheless, no fishery exists in regions X and XI.

27.2.1 *Argopecten purpuratus* (Lamarck 1819) the Northern Scallop

Grau (1959) changed *Argopecten purpuratus* into *Chlamys (Argopecten) purpurata*, and several authors have used this classification. But Waller (1969) states that this scallop species is the southernmost representative of the *Argopecten* group originated in the tropical / subtropical region of the Caribbean and Atlantic. Wolff (1987) studied the population dynamics of this scallop species during the El Niño phenomenon in Perú, and he states that these animals resemble very much the bay scallop *Argopecten irradians* from the Northern Pacific in its population parameters, and he argues that his findings support the conclusion made by Waller (1969). On the other hand, von Brand et al. (1990) studying the chromosomes of the Northern Chilean scallop also agree with Waller (1969) and Wolff (1987) that this species belongs to the genus *Argopecten* and not to *Chlamys* using again the original species name proposed by Lamarck 1819, *Argopecten purpuratus*.

Some authors have described the distribution of this species along the Pacific coast from Corinto, Nicaragua to Valparaíso, Chile (Navarro et al. 1990), and from Panamá or Nicaragua to the X Region in Chile (40 °S). However, this information is quite inexact, because this species has never been found in Panamá nor any other country besides Perú and Chile (Villalaz, pers. comm.). The most important banks are located between Bahía Sechura - Perú (6° S) and Bahía Tongoy - Chile (31° S) (Vildoso and Chirichigno 1956; Marincovich 1973, Peña 2001) (Fig. 27.1). Individuals have been found as far south as the V Region, south of Valparaíso. The main banks in Chile are actually found in Bahía San Jorge, La Rinconada (Antofagasta, region II) and Bahía Tongoy (region IV). It is important to point out that in the last decade various specimens were transferred to the South of Chile (Puerto Montt and Chiloé, region X) for aquaculture purposes, but no natural populations exist there.

Natural populations of *A. purpuratus* are found in sheltered zones from 5 to 40 m depth, especially in protected inshore bays with a low water exchange rate (Illanes 1990). Reproductively the northern scallop is a functional hermaphrodite with external fertilisation. The female and male gonads have simultaneous maturation, and it is very common that spermatozoa are released before oocytes during spawning periods (Uriarte et al. 2001). Partial or total spawnings occur all year round, with peaks in spring - summer (November-March). *A. purpuratus* has ideal characteristics for cultivation, which favoured its development as a new species to be reared by aquaculture methods in the early 1980's. This species has a fast growth, reaching the commercial size of about 75–80 mm shell height in about 18 months. Another advantage is that it is a native species, which shows a good survival in its original distribution area and has high commercial value.

27.2.2 *Zygochlamys patagonica* (King and Broderip 1831) the Southern Scallop

Zygochlamys patagonica was originally named *Chlamys patagonica* by King and Broderip (1831), and was transferred into the *Zygochlamys* genus by Waller (1991). It can be found in Chile (Fig. 27.1) from Puerto Montt (region X) to Punta Arenas (region

XII), and to the Magellan Strait (56° S) and Puerto Quequen in Argentina (Navarro et al. 1990). This scallop lives in protected bays, inlets, and channels between 2 to 40 meters deep, as well as in depths over 100 m on the Argentinean platform, where this species sustains a very important fishery in the last few years (Lasta and Bremec 1999). This species has separate sexes, without sexual dimorphism. The salinity in their natural areas fluctuates between 21 to 29‰, and the water temperature between 6 to 10°C. This species is not under commercial aquaculture production so far, therefore all of the captures are obtained from fisheries.

27.2.3 *Chlamys vitrea* (King & Broderip, 1831) the Southern Scallop

This bivalve has separate sexes, being a very mobile species, which in its early life swims around in the seaweeds (Walossek 1991). The shell is translucent whitish or orange in individuals up to 50 mm shell height, later on the shell increases in height and convexity, as well as thickness, attaining a dark brown or violet colour, even in the interior of the valves. Considering these dramatic changes in morphology, it is not surprising that this species has been described as various different species (Walossek 1991). *C. vitrea* is a species, which lives in the shallower parts of fjords, closely related to glaciers, between 48° and 55° S. Guzmán et al. (1999) observed that beds are between 2–17 m deep, with densities between 5–20 individuals m⁻². The growth parameters estimated by Guzmán et al. (1999) are $L_{\infty} = 100\text{--}107$ and $K = 0.23\text{--}0.27$, demonstrating to be a slow growing species.

27.3 FISHERIES

27.3.1 *Argopecten purpuratus*, the Northern Scallop

Historically, production of the Northern scallop was an extractive activity carried out by artisanal fishermen from the natural populations or “banks” located in North and South Chile. These have been exploited since the pre-Columbian times, and shells have been found at archaeological sites. In the period from 1945 to 1980, the fishery of *A. purpuratus*, the only valuable scallop species at that time, remained at a low level, with landings not exceeding 500 metric tons (t) per year (Fig. 27.2 and 27.3). This volume was used only for internal markets. The first fishery collapse occurred during early 1950, when annual landings did not surpass 400 t. Natural stocks of *A. purpuratus* were already overexploited in 1958, and therefore Chilean authorities applied successive administrative measures trying to avoid a total depletion of the resource, which ended with an indefinite ban of extraction from Arica to Valparaíso to protect the species (Lorenzen et al. 1979; Avendaño and Cantillanez 1996). These management measures were not, however, enough to recover the natural scallop stock. During 1962, only 11 mt of scallops were landed (Hancock 1969). These low captures forced to impose a new period of prohibition in 1971 that was extended until 1975. In the late 1970’s, the government developed an active policy to supply international markets with fishery products. As a result, a sharp increase was observed after 1981, and in 1982, regular exports of

Figure 27.2. Scallop landings of fishery and aquaculture in different regions of Chile.

Figure 27.3. Comparison of total landings of fishery and aquaculture in Chile.

A. purpuratus began (Avendaño and Cantillanez 1996), with scallop landings reaching $5,276 \text{ t yr}^{-1}$ in 1984. This increase was favoured by a good recruitment in northern Chile in 1983 due to the El Niño, a phenomenon well described for scallops on the Peruvian coast by Wolff (1987). But the fishery could not be sustained at that level, and landings decreased in the following years. In order to prevent another collapse, several regulations, including minimum size of capture and closed seasons were decreed by fishery authorities. Nevertheless, as no recovery was registered, the fishery was completely closed in 1988, and has remained closed since then, with a prohibition renewed on a two-year basis.

As shown in Fig. 27.2, the landings fluctuated heavily among years, which is probably caused by strong variations in the magnitude of settlement and recruitment. The strong recruitment during the 1983 “El Niño”, as already mentioned, sustained high landings during the years 1984–1985 in most parts of the country (Fig. 27.2). However, this high fishing effort (and landings) could not be sustained during the following years. The heavily overexploited stocks were unable to produce a minimum amount, and the fishery had to be closed completely. The closure of the northern scallop fishery was the main incentive to develop and initiate the aquaculture of this species, an activity that began experimentally around 1985. The first harvests of cultured scallops were registered in 1989. However, as pointed out by Stotz and González (1997), at this time the aquaculture represented to some extent also the landing of illegal extraction of individuals from the natural scallop beds. These individuals collected were considered as “seed” for cultures, understanding all available sizes as “seed”.

A. purpuratus is a fast growing and productive species. In Tongoy Bay the main settlement period occurs at the end of summer or beginning of autumn (February–April). The individuals grow to 90 mm shell height (minimum legal size for fisheries) in 18 months; the growth parameters being $L_{\infty} = 124.58$ and $K = 0.84$ (Stotz and González 1997). The production estimated for Tongoy Bay, with a low density of 1.64 individuals m^{-2} due to fishing, was of $0.528 \pm 0.238 \text{ kg m}^{-2} \text{ yr}^{-1}$ ($P/B = 2.08$). With optimal management, maintaining a standing stock of 10 individuals m^{-2} , a production of $32 \text{ t ha}^{-1} \text{ yr}^{-1}$ is estimated, allowing an annual yield of 3.2 t ha^{-1} (Stotz and González 1997).

Scallops are collected by hand. The fishermen dive to a maximum depth of 20–25 m, with the aid of an air compressor on a boat (“Hooka” diving) using boats of 5–7 m length, with outboard motors of 15–45 HP).

27.3.2 *Chlamys vitrea* and *Zygochlamys patagonica*, the Southern Scallop

The fishery of the Southern scallop species was assumed to be capturing *Zygochlamys patagonica*. Only individuals bigger than the minimum size of capture of 75 mm were fished. This differed significantly from what was known for the species from the Argentinean Continental Shelf, where the maximum sizes (L_{∞}) were below this level (54.4–74.6 mm). Doubts regarding the identity of this species fished in the Patagonian region appeared. Valladares and Stotz (1996) demonstrated through an experimental research that the growth of *Z. patagonica* in the Patagonian region was similar to that

described for the Argentinean fishery, with an $L_{\infty} = 63$ and $K = 0.75$. Thus, the fishery was really capturing another species, which was identified as *Chlamys vitrea*.

C. vitrea is a species, which lives in the shallower parts of fjords, closely related to glaciers, between 48° and 55° S. Guzmán et al. (1999) observed that the beds are located between 2–17 m depths, with densities between 5–20 individuals m^{-2} . The growth parameters estimated by Guzmán et al. (1999) are $L_{\infty} = 100$ –107 and $K = 0.23$ –0.27, demonstrating it to be a slow growing species.

Z. patagonica lives in greater depth, but shallow beds can also be observed. Guzmán et al. (1999) sampled beds between 12–25 m, with densities between 3–50 individuals m^{-2} . Valladares and Stotz (1996) worked in a bed with a distribution between 5 to 25 m depth. On the Argentinean Continental Shelf, the species lives at a depth around the 100-m isobath (Lasta and Bremek 1999). Probably similar deep beds of the species exist in fjords in the Patagonian region, but no survey at such depth is known.

The minimum legal size of capture of 75 mm was only maintained for *C. vitrea*, being lowered for *C. patagonica* to 55 mm. Nevertheless, the fishery statistics still does not distinguish between both, giving only one figure for both species together. The landings were increasing until 1998, when they reached the level of 3,662 metric tons, but in the following year they decreased to 1,715 t suggesting that the maximum productive capacity of both species have already been reached. Extensive beds of *Z. patagonica* may exist at greater depths than those where diving is allowed (20 m). These could probably be fished using dredges. The Chilean law, however, completely prohibits fishing with dredges, as it is assumed to damage the benthic communities. Scallops are only allowed to be hand collected by divers, which work from 7–9 m boats equipped with air compressor (Hookah diving). Those beds, probably existing at greater depths are protected from fishery and will always serve as a reserve, which can provide larvae and settlers to the beds that are exploited. On the other hand, *C. vitrea*, which only lives in shallow water in fjords, is more exposed as a species to be harmed by fisheries. First attempts were made by the Universidad de Magallanes (region XII) to culture this species, and in this way assure its production. These attempts are still at a laboratory scale, with no commercial production until now.

27.4 HOW SCALLOP AQUACULTURE STARTED IN CHILE

The scallop aquaculture in Chile has a history of approximately 28 years starting with the first studies carried out by Hogg (1977), who made the first growth experiments in natural environment. One year later, Bustos (1978) obtained more information about seed collection. The first laboratory results were recorded by Sanzana (1978) studying the cycle of gonadal maturation and cultivating the first larval stages. Padilla (1979) followed with the culture of larvae in laboratory. While these were the first attempts at learning about the scallop *Argopecten purpuratus*, it was really in the early 1980's when research began with the main purpose to find a technical viability to produce the Northern scallop using aquaculture methods (Akaboshi and Illanes 1983). DiSalvo et al. (1984) were able for the first time to produce Chilean scallop larvae under controlled conditions. The next step was to find a way to produce them on a commercial scale, and the answer came from

Japan. The technology used to farm Japanese scallop (*Patinopecten yessoensis*) was introduced in Chile and applied successfully to the Northern scallop, *Argopecten purpuratus*. Three different organisations joined their efforts to develop commercial scallop farming, the Universidad [Católica] del Norte (Coquimbo, Chile), JICA (Japan International Cooperation Agency) and the Subsecretaría de Pesca (Governmental Agency for Fisheries and Aquaculture, Chile). The purpose of this joint effort was to start the necessary basic and applied research to develop the Northern scallop aquaculture under controlled conditions and in natural environment. Once the Japanese technology was adapted to the Northern scallop and tested in Tongoy Bay, the knowledge and technology developed was transferred to the productive sector (Illanes 1990; Vega 1996; Uriarte et al. 2003). In the following year, the OFCF (Overseas Fishery Corporation Foundation), the Subsecretaría de Pesca and SERNAP (Servicio Nacional de Pesca – National Fisheries Service, Chile) also started a project in Tongoy Bay to develop a new culture technology for *Argopecten purpuratus*. In 1984, the first controlled scallop production was 57 t from 6 culture centres (Vega 1996; Uriarte et al. 2003). But Stotz and González (1997) state that this production was possibly due to illegal landings because the production process still had several flaws. During the first attempts to start the commercial aquaculture production, the main restriction happened to be the seed source. Therefore a hatchery technology to produce good quality seed was developed as a response to the need of regular seed supplies for growers. Nowadays, the scallop producers in Chile, mainly private producers, have two seed sources: collecting them from the natural environment (80%) and hatchery production (20%) (Illanes 1988; Bourne et al. 1989; Abarca 2001; Uriarte et al. 2001).

The results from the first experimental-pilot hatcheries showed problems related to larval survival, settlement, metamorphosis and postmetamorphic culture or nursery. During the decade of 1980, the biggest constraint to the acceleration of the Northern scallop aquaculture development was the high degree of investment required and difficulties to determine or adapt different ranges of scallop production.

In 1985, the Universidad [Católica] del Norte and the Japanese Government through JICA built the Coastal Center for Aquaculture and Marine Research, which meant a big step forward in research and development of hatcheries for marine invertebrates, specially bivalves. The Coastal Center was built with state of the art of Japanese hatchery technology with a pumping capacity up to $50 \text{ m}^3 \text{ h}^{-1}$, becoming the biggest and most technologically up-to-date facility of its kind in Latinamerica. The same year, CICUM (Centro de Investigaciones de Cultivos Marinos) belonging to a private fishing company, Pesquera Guanaye, built a hatchery and started its own scallop production in Antofagasta (Chile). Later Novamar (1986) appeared in Arica, and Biomar (1987) in Coquimbo. In 1989, six scallop hatcheries and 26 culture centres were operating, between region I and IV, with a production of 200 t (Illanes 1990). The commercial activities transformed themselves into one of the most important industries, mainly in the regions III and IV, and these regions were once considered the poor or marginal regions of Chile. Now they produce about 98% of the national scallop production (Sernapesca 2003).

Another big group of commercial and pilot hatcheries, Cultivos Marinos Internacionales was built in 1990 in region III, becoming the largest commercial hatchery

in the country. Later, Pesquera Camanchaca (1992), Cultivos Marinos Guayacán (1993), Aquaingeniería (1994), Pesquera San Jose S.A., Cultivos Flamenco and Hidrocultivos (1995) were added, located in the regions III and IV. In addition, in the south of Chile (region X, 40° S) the hatchery of Cultivos Marinos Bahía Yal (1996) started culturing *A. purpuratus*; a region where the Northern scallop is not naturally distributed. Lately, new information has been obtained on growth and survival of *A. purpuratus* larvae from hatcheries in Southern Chile (Uriarte et al. 1996). Between 1985–1995, at least twelve to fourteen hatcheries were created, but several of these industries declined due to technical and probably economical problems (Vega 1996). In 2001, approximately twelve scallop hatcheries of different types and sizes produced *A. purpuratus* spat between regions II and X in Chile (Abarca 2001).

Most of the scallop production is for export, reaching markets such as France, USA, Belgium, Germany, Argentina and Asia. The production in Chile has gradually increased up to twenty times between 1989 and 1999, and now the country is considered the third scallop aquaculture producer worldwide, after China and Japan (Table 27.1). In 1999 a total of 22,383 t of scallops were harvested and 92% came from cultivation and extraction by artisanal fishermen of the Northern scallop. It seems that Northern scallop production reached a plateau after 1999 with a production range between 15,000 to 19,000 t (Table 27.1). The landings of the Southern scallop (*Zygochlamys patagonica* and probably *Chlamys vitrea*), come exclusively from artisanal fishery and not from aquaculture (Fig. 27.2). The highest capture peak has been of 3,662 tons in 1998, and the capture descended later to 1,715 t in 1999 (Sernapesca 1999). This predicts that Chilean aquaculture follows the activity's world trend of production.

27.5 AQUACULTURE PRODUCTION

The scallop hatchery culture involves broodstock conditioning, spawning, fertilisation, larval culture, settlement and metamorphosis and seed growth up to commercial size (Navarro et al. 1991; Merino et al. 2001). Each one of these stages of the production cycle has different time lengths (Table 27.2), depending on the biology of the species (Narvarte et al. 2001), physical and chemical conditions of the water (Uribe and Blanco 2001) and other factors such as biofouling (Uribe et al. 2001).

The culture technology used in Chile is based on the Japanese system developed in the 1960's and it is basically a suspended culture on floating structures called "long-lines" (Merino et al. 2001). To collect seed, "collector bags" are used to capture natural larvae in the wild prior to settlement (Narvarte et al. 2001) (Fig. 27.4). Trays known as "pearl nets" for the intermediate culture and structures for the final culture step called "lanterns" (Fig. 27.4). All the procedures described below are focused exclusively on the Northern scallop *Argopecten purpuratus*. This scallop is the only one being intensively produced in Chile by the aquaculture industry (Merino 1997).

Table 27.2

Culture systems and densities used in some scallop production centres in Tongoy Bay, Chile.

Culture system	Density (scallops / system)	Scallop size (mm)	Time (days)
Collector bag	variable	7–11 (out)	60–90
Pearl net 4.5 mm	150	7–11 (in)	90–120
Pearl net 9 mm	30–40	20–30 (in)	120
Lantern net 12 mm	30	30–40 (in)	60–90
Lantern net 21 mm	20–30	50–60 (in)	90–120

Figure 27.4. Different culture systems used for *Argopecten purpuratus* in Tongoy Bay, Chile. From left to right: collector bags, small lantern net, pearl nets and large lantern net.

The production cycle is usually between 14 to 18 months from fertilisation, reaching a commercial size of 75 to 85 mm in shell height. It has been established that scallops older than 18 months do not increase significantly in meat yield, because beyond this age they devote most of their energy to reproduction, showing more maturation peaks than younger individuals, not leaving much energy for meat growth.

27.5.1 Production Stages

27.5.1.1 Hatchery broodstock conditioning and spawning

Adults used as broodstock are brought into the hatchery, cleaned from biofouling and placed into clean running seawater in separate tanks for spawning. Depending on the developmental stage of the gonad, an adequate amount of microalgae must be given to reach full ripeness (Uriarte et al. 2001). The assessment of maturity, before the spawning stimulation starts, can be made in several ways. A simple, non-destructive method is a visual inspection of the state or condition of the gonads. The more conventional, destructive method is the gonad index (wet weight of gonad in relation to the total wet weight of the soft parts $\times 100$). Generally, a full and bright orange gonad or a gonad index over 20% is desirable for successful spawning. A constant water flow is needed to maintain a suitable level of dissolved oxygen in the seawater ($>7-8 \text{ mg L}^{-1}$). Bourne et al. (1989) mentioned water flow rates of 10 L min^{-1} for *Patinopecten yessoensis*. Seawater used for all phases of spawning must be filtered to at least $5 \mu\text{m}$. The most used technique to induce spawning is thermal stimulation by increasing the temperature between 5 to 7°C (Bourne et al. 1989). If thermal stimulation does not work, as alternative solution chemical inducers like serotonin applied by intramuscular injection to promote sperm release can be used (Bariles and Gaete 1991). Chemical induction does not have widespread use in commercial hatcheries where thermal induction is preferred. To have successful fertilisation, DiSalvo et al. (1984) suggest the use of a proportion of 10 spermatozoa per oocyte for *A. purpuratus* to avoid polyspermy. Some small experiments using a much higher number of sperm cells did not show polyspermy in this species (Bellolio and Lohrmann, pers. comm.).

During the fertilisation period, it is advisable to use only $1 \mu\text{m}$ filtered and UV treated seawater. During this time no feeding and additional air supply are required. Approximately 48 h after fertilisation, the first larval stage, "D" larva, is reached.

27.5.1.2 Larval stage

The scallop begins its life as a free swimming or planktonic larva, but with a totally different behaviour and physical appearance compared to juvenile and adult scallops. The larvae can be cultivated in differently shaped tanks like conical cylinders, rectangular or cylindrical tanks. The most used tanks are the conical - cylinder with a drainage exit at the bottom. Water should be filtered, at least to $5 \mu\text{m}$ and UV treated. During this time the larvae require a fair amount of microalgae as live food. Many species of microalgae have been cultivated and used in hatcheries (Table 27.3). They can be divided in two

groups: flagellated and diatoms. Most of the species commonly used in the hatcheries are known worldwide and recognised as species of easy culture and nutrition value (Uriarte et al. 2001). For the water changes, sieves of nylon mesh are used to retain the larvae. As far as possible, it is advisable to record some physical, chemical and biological factors like temperature, pH, salinity, dissolved oxygen, the amount of food, bacteria and others.

The larval period can last between 16 to 25 days depending upon water temperature, and the amount and quality of microalgae used. The final step is the pediveliger or eyed larva with a size of 230 µm. The morphological characteristics of this larva are the presence of a very well developed "foot" and an eyespot.

27.5.1.3 Settlement, metamorphosis and postlarval stage

The larval stage ends when the larva has settled on a prepared substrate, and it begins metamorphosis that will end as a small juvenile scallop. This new stage is not planktonic, and therefore the animal remains at the bottom of the sea or lightly attached on a prepared substrate within the culture tank, but eventually "swims" shaking its valves. During the metamorphic process, the animal stops food intake and starts using the energetic reserves accumulated during the larval stage. Under laboratory conditions, the process of settlement and metamorphosis takes between 2 and 5 days at 18–20°C. In some cases the substrate (collector bags) is kept for 3 to 5 days before larval settlement in seawater with microalgae to generate a microbial film on the surface to facilitate a natural induction to settlement (Narvarte et al. 2001). The use of artificial inducers at an industrial scale is still under evaluation from an economic and environmental point of view. After larval settlement is completed, the collector bags are transferred from the hatchery to a long-line (Illanes 1990; Merino 1997; Merino et al. 2001). Collector bags remain about 60 to 90 days in the sea, depending on the time of the year, until the scallops reach 6 to 8 mm in length (Abarca, pers. comm.).

Table 27.3

Common microalgae species used in scallop hatcheries.

Species	Class	Scallop size	Recommended use
<i>Chaetoceros calcitrans</i>	Baccilariophyceae	2.5–3.75	Larvae
<i>C. simplex</i>	Baccilariophyceae	8.0–9.0	Juveniles, adults
<i>C. gracilis</i>	Baccilariophyceae	5.0–10.0	Juveniles, adults
<i>Thalassiosira pseudonana</i>	Baccilariophyceae	2.5–10.0	Juveniles, adults
<i>Skeletonema costatum</i>	Baccilariophyceae	6.3–10.0	Juveniles, adults
<i>Isochrysis</i> sp. (var. <i>Tahiti</i>)	Prymnesiophyceae	3.3–5.75	Larvae, juveniles and adults
<i>Pavlova lutherii</i>	Prymnesiophyceae	3.5–6.5	Larvae, juveniles
<i>Tetraselmis</i> sp.	Prasinophyceae	8.0–12.0	Juveniles, adults

27.5.1.4 Seed supply

Seed can be obtained from two sources: natural populations and hatchery. Natural stocks provide either eyed larvae (D larvae) or juveniles. The collector system consists of plastic mesh bags (generally Netlon™), which are suspended from a long-line to form a curtain or barrier to the passing of the swimming larvae in the water column. The time between settlement and metamorphosis in the collector bags will be mainly regulated by environmental temperature and occurs at least between 15 to 20 days after spawning in the wild (Illanes 1990). Each scallop farming company or culture centre usually has an exhaustive monitoring system to sample and record the quantity and size of Northern scallop larvae in the plankton to determine the moment when collector bags have to be deployed in the ocean. Collector bags are hung from a long-line for 2 to 3 months, which allow the settled scallops to reach around 7 to 9 mm before being transferred to the next culture stage in an intermediate culture systems (Table 27.2, Fig. 27.4). Keeping collector bags for periods over 3 months in the sea is not recommended since high mortality by predation, fouling and loss of the collectors due to excessive weight have been reported. Wild seed collection shows seasonal and interannual variability in the abundance of seed due to fluctuations of environmental conditions (Abarca et al. 1999). The presence of scallop larvae in collector bags are not time-constant, because they are influenced by environmental conditions like larval density, weather conditions, water temperature, transparency, salinity, currents and other biotic and abiotic factors of the natural spawning area. The quantity of seed captured in collector bags is highly variable from one year to another (Pereira and Molina 1997; Narvarte et al. 2001). The predictability of larvae in natural environment was the first and main bottleneck to enhance the industrial farming of the Northern scallop. Generally, during spring and summer all the scallop farming companies deploy collectors in the oceans on long-lines to catch natural larvae. If there are not sufficient larvae available in the wild, then hatchery practices are required to supply them. Hatcheries can get their broodstock from their own on-growing systems or from other producers. In Chile, a total of 13 commercial scallop hatcheries exist (Abarca, pers. comm.). Chilean Northern scallop hatcheries can produce almost all year around, which guarantees a constant supply of seed to the growers during the year and allows the possibility to have a planned production system. Natural seed sources are not constant in spawning time or amount of seed yielded.

27.5.1.5 Ongrowing stage

During the intermediate culture step, the seed between 7 and 9 mm are selected and transferred from the collector bags to pearl-net systems for at least 3 to 4 months, depending on the type of pearl nets used and the conditions of the culture area, near or far from the beach. The final stage of culture begins with the transfer of scallops from pearl nets to lantern nets for a period of 5 to 7 months (Table 27.2, Fig. 27.4) (Merino et al. 2001).

There is another culture system which is sometimes used for the final stage that is called “ear-hole”, where a hole is drilled into the “ear” of the scallop and a plastic filament

is used to hang the animal to a rope (Fig. 27.5). The “ear-hole” method is inexpensive, but has the risk of serious biofouling, which might lead to partial or complete loss of scallops due to a rupture of the “ear” when oceanographic conditions are not calm.

The ongrowing stage takes approximately 12–15 months after the seed stage is completed (out of collector bags). At the end of the first year starting from fertilisation, at about 40 mm shell height, they reach first reproductive maturity, and during their second year they reach the commercial size of 75 to 85 mm, depending upon the natural conditions of the growing area. Cultured animals can be harvested before, however, with smaller sizes if the market requires them.

27.5.2 Constraints and Opportunities for Northern Scallop Hatcheries

The development of scallop hatcheries has been marked by the following aspects:

- a) hatcheries are not a high-priority as long as natural collected seed are available, cheaper and able to sustain the business;
- b) the evolution of scallop prices on the international markets has not favoured new investments;

Figure 27.5. “Ear hole” culture system used in Tongoy Bay, Chile.

- c) not many adequate and useful coastal areas exist with basic conditions such as electrical energy, fresh water or communications to install hatcheries;
- d) the cyclic oceanographic fluctuation of El Niño and La Niña phenomena are responsible for the variation in collection of seed from nature. The El Niño phenomenon with its increase of water temperature produces an increase in spawning peaks, and finally a high seed production (Illanes et al. 1985; Merino et al. 2001). The La Niña with a decrease in water temperature produces exactly the opposite.

Nevertheless, some private companies have decided, on a long-term vision, to maintain or create new hatcheries to provide stability in seed availability, but with expensive seed. Scallop hatchery information is often limited for many reasons. The results have not always been better and finally the cost of hatchery seed is higher than those collected naturally (Illanes 1990). Considering the latter statement, hatchery-produced seed can have the following advantages:

- a) to complement the natural collection;
- b) to maintain a constant supply, even when environmental conditions are not favourable;
- c) to allow early genetic selection and / or manipulation to produce better offspring (von Brand and Ibarra 2001).

Lastly, in a three-year study Abarca et al. (1999) found that the performance of hatchery seed compared with those from wild collection showed that 46.4% and 56.65% survive until harvest, respectively. Hatchery seed appears to be weaker than wild seed due to its “artificial nature”. Some private companies that run hatcheries obtain up to 20 to 40% of the total amount of seed from hatcheries.

27.5.3 Interaction between Natural Beds and Aquaculture

Aquaculture of Northern scallop began through a special regulation, which guarantees farming companies some kind of ownership of a given seawater area to fulfil aquaculture activities. The seawater aquaculture concessions were granted in the same bays in which natural beds exist or existed. For example, in Tongoy Bay (which has a total surface of 3,600 ha) 1,900 ha were given to private enterprises to develop scallop culture. In this way, the space for recovery of wild scallop beds was greatly reduced. Moreover, on the open grounds, scallops were subjected to an intensive clandestine fishery and then sold as seed for ongrowing culture (Navarro et al. 1991; Wolff and Alarcón 1993; Stotz and González 1997). Thus, in spite of the closure of the fishery, beds did not recover. On the contrary, they were almost completely destroyed (Stotz 2000).

In the meantime, the cultures developed very rapidly, the harvests of cultured Northern scallops in the regions III and IV in 1999 already representing almost 10–20 times the volumes landed by fishery in the past (Fig. 27.3). A survey of stock sizes in natural beds and in cultures, shows that the wild stock already represents only 2–9% of the total stock in Tongoy Bay, or at best 10% in the entire country, being most of individuals in sea farms. This leads to the conclusion that *A. purpuratus* already represents a “domesticated” species (Stotz 2000). In this context, and considering the occurrence and

development of selection practices in sea farms, genetic variability within the species appears to be at risk and already problems are showing up. As the faster growing individuals are harvested up to a year earlier than the slowest growing individuals, they contribute less to reproduction, with the result of an involuntary selection in favour of slower growing individuals. As a consequence, the increasing occurrence of dwarfs (very slow growers) in culture is mentioned as a problem by some sea farmers (Stotz 2000). For proper conservation of genetic variability, one possibility is to protect and restrain management of some wild populations. One reserve has already been established in region II (Avendaño et al. 1997). Other reserves in the more productive regions III and IV have not been considered, yet.

27.5.4 Recovery of a Natural Bed of *Argopecten purpuratus*

The Chilean fishery law of 1992 incorporates the possibility for fishermen to get exclusive fishing rights in limited coastal zones, called “management areas”. In 1991, while the law was still in discussion, the Fishermen Union of Puerto Aldea, (region IV), a small fishing village on the southern corner of Tongoy Bay (Fig. 27.1), decided to protect the area in front of the town. Within few years the Puerto Aldea scallop bed increased its density and biomass, reaching by now a medium density of 4.74 individuals m^{-2} and a biomass of 0.572 kg m^{-2} (results of a direct stock assessment done in August 2000 by Stotz). Nevertheless, this recovery probably is closely related to the reproduction of the scallops maintained in sea farms, which, as mentioned before, represent between 91–97% of the scallops in Tongoy bay. Thus, we cannot really talk of the recovery of a true wild stock at Puerto Aldea. Therefore, and with the aim of conservation of genetic variability, natural beds in bays or sites not related to scallop sea farms need to be found. But the “management area” system represents a way to recover the productivity of scallop stocks in open areas within bays with sea farms. According to figures given by Stotz and González (1997) to the present, production of region IV, which amounts in 1999 to 13,793 t, the well managed “management areas” within Tongoy Bay could add another 11,200 t, thus completing a total production of around 25,000 t for the region. The management should include a restocking to an average density of 10 individuals m^{-2} , and limit the fishing rate to 10% of the total production of the stock. For restocking only protection of the bed is needed, but the introduction of seed collection techniques used in sea farms could improve the restocking. In the latter case, genetic selection for restocking areas should be considered, to avoid a loss of genetic variability due to the use of inadequate seed.

27.5.5 Final Overview and Projections of Chilean Scallop Farming

Actually, 27 companies are dedicated to the culture of this scallop species, 13 hatcheries producing seed and approximately 8 institutes and universities are involved in basic research like biology, reproduction physiology, nutrition, genetics, pathology (parasitology and microbiology), and technological aspects and bioengineering for farming facility systems design. The interaction among institutes, universities and the

production sector is becoming more important, and many research projects are increasingly involving companies, trying to solve “real” farming and operational problems.

About 3,000 permanent and 1,000 temporary jobs are associated with the Chilean scallop industry (Fig. 27.6). On the other hand, the great development of this industry has allowed the direct or indirect development of new supply companies, which are producing pools, boats (Fig. 27.7), operational task rafts (Fig. 27.8) and operational docking areas. Also, an improvement of quality in products like plastic mesh, ropes, etc. has occurred.

Figure 27.6. An important amount of workers are required to support daily farming operations both in sea farming systems and land operation systems. Northern scallops are being introduced into pearl-nets in a land docking management area.

Figure 27.7. Aquaculture boats equipped with hydraulic cranes are being used to lift lantern nets from the long-line.

Figure 27.8. Task raft developed for scallop culture in Tongoy Bay, Chile. On this raft, culture steps such as selection, cleaning and change from one culture system to another are performed.

ACKNOWLEDGMENTS

We want to thank Leandro Sturla for his comments and Dr. Karin Lohrmann for her help with the manuscript.

Chapter 28

Venezuela

César J. Lodeiros, Luis Freites, Maximiano Nuñez, Anibal Vélez and
John H. Himmelman

28.1 INTRODUCTION

The Venezuelan coast, in the southwestern Caribbean Sea (Fig. 28.1), is a tropical region that supports a high diversity of bivalve molluscs. To date, more than 200 species of bivalves have been catalogued (Lodeiros et al. 1999). These include ten species of pectinids: *Chlamys ornata* (L., 1758), *Chlamys muscosus* (Wood, 1828), *Aequipecten lineoralis* (Lamarck, 1819), *Euvola (Pecten) ziczac* (L., 1758), *Leptopecten bavayi* (Dautzenber, 1900), *Argopecten nucleus* (Born, 1780), *Lyropecten (Nodipecten) antillarum* (Rélu, 1853), *Nodipecten (Lyropecten) nodosus* (L., 1758), *Amusium papiraceum* (Gabb, 1873) and *Amusium laurenti* (Gmelin, 1791). Most of these scallops are small (<40 mm shell height) and only *Nodipecten nodosus* and *Euvola ziczac* are exploited by coastal populations for local consumption and *Amusium papiraceum*, *Amusium laurenti* and *Argopecten nucleus* are exploited by a drag fishery.

Following the increase in demand for scallops in the 1980s, the Instituto Oceanográfico de Venezuela of the Universidad de Oriente began experimental studies on Caribbean scallops, principally in the Golfo de Cariaco (Fig. 28.1).

28.2 DISTRIBUTION, HABITAT AND REPRODUCTION

28.2.1 *Euvola (Pecten) ziczac*

This large semicircular species can attain up to 90 mm in shell height. The upper (right) valve is almost flat (slightly concave in the central region) and the lower (left) valve is strongly convex. The upper valve is ornamented with zigzag lines. Both shells are usually brown but occasionally purple or orange, and white for rare albino individuals (Lodeiros et al. 1999). *Euvola ziczac* is found in the western Atlantic, from North Carolina (eastern United States) and Bermuda to Santa Catarina in southern Brazil. In Venezuela, it is most common along the northeastern coast.

Euvola ziczac forms small beds on sandy bottoms in areas of upwelling. In contrast to the other scallops in the region, *E. ziczac* is an infaunal species. It buries itself flush with sand bottoms, with its upper valve covered with sand. As a result it cannot be easily seen, although the semicircle of fine tentacles, which extend above the substratum can be seen upon close inspection (Fig. 28.2). The burying behaviour of *E. ziczac* potentially camouflages it from predators and it readily swims when touched by certain predators

(Brokordt et al. 2000). Its main predators are gastropods of the genus *Cymatium* and the octopus *Octopus vulgaris* (shells are often abundant near octopus dens).

Figure 28.1. Location of Turpialito, Golfo de Cariaco, where most of the studies on Venezuelan scallops were performed.

Figure 28.2. An unburied scallop, *Euvola ziczac*, a swimming scallop, and two scallops in their usual position, buried flush with the sediment surface (only a circle of tentacles is visible).

In natural beds of *E. ziczac*, most individuals measure between 60 and 88 mm in height (Fig. 28.3) and juveniles are found in extremely low densities. This suggests that scallops settle in areas outside of beds and later move to the beds.

Euvola ziczac is a functional hermaphrodite and is unusual among tropical bivalves because of its markedly seasonal reproduction. Active gonadal development and spawning occur between January and September and is followed by a period of reproductive inactivity between October and December (Brea 1986; Vélez et al. 1987). The reproductive period coincides with lower temperatures and high primary productivity, due to upwelling, and the period of reproductive inactivity with high temperatures and low productivity, associated with stratification of the water column (Lodeiros and Himmelman 1994). Natural populations of *E. ziczac* spawn twice, first in April to May and secondly in August to September, and during each spawning most individuals release gametes synchronously (Brea 1986; Vélez et al. 1987; Brokordt et al. 2000). Although Vélez et al. (1993) indicate that temperature is the major factor controlling gonadal maturation and

Figure 28.3. Size composition of a population of *Euvola ziczac* at Chacopatica in the Golfo de Cariaco, Venezuela, based on all individuals encountered during 8 hours of diving (two divers). No individuals were found measuring <40 cm.

spawning in *E. ziczac*, an inconsistent relationship between temperature and spawning has often been observed during culture studies (Vélez et al. 1995; Lodeiros and Himmelman 2000). For example, spawning may occur in one culture treatment but not in others, even though all are exposed to the same temperature. This suggests that the conditions in the immediate vicinity of the scallops, rather than large-scale factors, strongly influence reproduction. Spawnings outside of spawning periods on natural beds have also been documented for scallops in culture (Vélez et al. 1995; Lodeiros and Himmelman 2000). Finally, Lodeiros and Himmelman (2000) show the size (shell length or height) at which gonads first develop in juveniles in suspended culture varies with both culture depth and environmental conditions (including the abundance of fouling organisms).

Several studies indicate that reproductive investment and high temperatures may lead to stress in *E. ziczac*. For example, Boadas et al. (1997) documented a decreased oxidative capacity of mitochondria from the adductor muscle in the major reproductive period in May, which appeared to be related to a depletion of muscle reserves by gametogenesis during the period of low food availability and high temperatures. Further, Brokordt et al. (2000) showed that although *E. ziczac* maintains its clapping capacity in response to predators (which allows it to escape by swimming) during the various reproductive phases, its ability to recover from exhaustive clapping decreases during the course of gonadal maturation and spawning. This decrease is greater during the first

reproduction (May) than the second reproduction (August), and this is likely explained by the greater gonadal production, coincident with lower food availability, during the first reproduction. Finally, a number of culture studies provide evidence of stress and mortality of adult *E. ziczac* during periods of high temperature and spawning activity (Lodeiros and Himmelman 1994, 2000; Boadas et al. 1997).

Natural populations of *E. ziczac* along the northeast coast of Venezuela show little genetic variability compared to most other pectinids, as Coronado et al. (1991) reported that the frequency of the polymorphic loci is 17.6% and mean heterozygosity is 0.074. The diploid number of chromosomes is 38 (Alfonsi et al. 1998) and studies by Pérez et al. (2000) of allozyme and biochemical variation at the octopine dehydrogenase (ODH) locus indicate that heterozygous superiority in fitness is the most likely explanation for an apparent over dominance at this locus.

28.2.2 *Argopecten nucleus*

This is a medium-sized scallop, up to 50–55 mm in shell height, with two similar convex valves, each with 10 to 22 robust radiating ridges. The colour is variable, but usually cream with brown patches (fewer brown patches on the lower valve). The juveniles attach byssally. *Argopecten nucleus* is similar to *Argopecten gibbus* (Linné, 1758), except that it has few additional ribs and a more globular shape (Lodeiros et al. 1999). *A. nucleus* occurs in southeastern Florida, the southern part of the Gulf of Mexico, and in the Caribbean and Surinam Seas and southward to the coasts of Guyana and Surinam. There are few data on its distribution in Venezuela, but it does settle on artificial collectors in the Golfo de Cariaco and the northern part of Sucre State and is occasionally captured in fishing drags.

Argopecten nucleus is a functional hermaphrodite. The one culture study on this species by Lodeiros et al. (1993) indicates that it is a short-lived scallop (8–10 months), which develops mature gonads at an age of about 6 months (at 38–48 mm in shell length). Thereafter, it reproduces continuously, even through periods of marked environmental changes, until about a month before it dies. In natural populations, individuals probably reproduce throughout the year, as larvae settle onto artificial collectors in all months (Lodeiros et al. 1997).

28.2.3 *Nodipecten (Lyropecten) nodosus*

This is the largest Caribbean scallop and attains sizes up to 150 mm in shell height. It has a strong rough shell with 7 to 9 wide nodular ribs and numerous longitudinal ribs. The auricles are asymmetrical and the colour is most often brown, but can also be purple to brownish red or orange. Juveniles can be confused with *Lyropecten antillarum*, which is a smaller scallop with a more fragile shell that does not have nodules (Lodeiros et al. 1999). *Nodipecten nodosus* is distributed from North Carolina to Brazil (Abbott 1974) but does not occur in Bermuda (Lodeiros et al. 1999). It occurs in low densities between 2 and 15 m in depth on coarse sand, or associated with corals, along the northeastern coast of Venezuela, but not in the Golfo de Paria.

Nodipecten nodosus is a functional hermaphrodite. Individuals in different reproductive phases are present throughout the year in populations along the Venezuelan Caribbean suggesting that it is constantly reproducing. Vélez et al. (1987) indicated a period of increased reproductive activity between August and December, but this was inferred only from changes in the biochemical composition of all tissues together (lipid content decreased during this period). Subsequent studies of individuals maintained in suspended and bottom culture showed gonadal decreases between May and July (Lodeiros et al. 1998; Acosta et al. 2000) and between October and November (Lodeiros et al. 1998; Freitas et al. 2001).

Populations of *N. nodosus* along the northeast coast of Venezuela show even lower generic variability than *E. ziczac*, as the frequency of polymorphic loci is 1.92% and mean heterozygosity is 0.0016 (Coronado et al. 1991). The diploid number of chromosomes is 38 (Alfonsi et al. 1998). Alfonsi et al. (1998) report that consanguinity probably affects growth rate but not survival and suggest that individuals produced by self-fertilisation are more sensitive than cross-fertilised animals to environmental conditions.

28.2.4 *Amusium papyraceum* and *Amusium laurenti*

Amusium papyraceum has slightly convex symmetrical shells that are fragile and attains up to 90 mm in shell height. The internal surface of both shells has 30–40 fine radiating ribs, whereas the external surface has a shiny periostracum and no ribs (Lodeiros et al. 1999). The upper valve is brownish red in colour and the lower valve is white. *Amusium laurenti* is similar to *A. papyraceum* except that it is smaller, up to 60 mm in shell height, has less prominent lateral auricles and only 20–22 fine ribs are visible on the inner surface of the shell (Díaz and Puyana 1994). Both *Amusium* species occur in the tropical western Atlantic, *A. papyraceum* from the Golfo of Mexico to northern Brazil, and *A. laurenti* only in the Caribbean, from Honduras to the north coast of South America (Díaz and Puyana 1994). *Amusium papyraceum* inhabits the eastern and northeastern parts of Venezuela and the main beds are found north of Isla de Margarita and on the coast of Sucre State. *Amusium laurenti* is only found in eastern Venezuela (Penchazade et al. 2000, Fig. 28.1). Both *A. papyraceum* and *A. laurenti* occur between 10 and 50 m in depth (with peak abundance at 30–36 m) mainly on sandy bottoms but also on sand-mud bottoms (Salaya 1977; Díaz and Puyana 1994).

Both *A. papyraceum* and *A. laurenti* are hermaphrodites and a portion of the populations have mature gonads throughout the year, although a major spawning takes place in June to July and some smaller spawnings in December to January and in March to April (Penchazade and Salaya 1980; Penchazade et al. 2000). Gonadal development of *A. papyraceum* begins when it attains 35 mm in shell height (Salaya 1977).

28.3 FISHERIES

Amusium papyraceum forms the major scallop beds in Venezuela and is fished commercially. Ninety-two percent of the landings from the industrial trawl fishery are from the northeastern region of the country, including Isla de Margarita and northern

Sucre State, and 8% from the Golfo de Venezuela (Novoa et al. 1998). Fisheries landings have varied greatly over the past 30 years (Mendoza et al. 1994, Fig. 28.4), from 10 to 750 t yr⁻¹ to peaks of 1,252 t yr⁻¹ in 1972 and 1,873 t yr⁻¹ in 1989 (data INIA 2001–Instituto Nacional de Investigaciones Agropecuarias de Venezuela).

Amusium papyraceum is part of a multi-species bottom trawl fishery, which targets shrimps, bottom fish and molluscs (octopus, squid and scallops). This mollusc first became important in the Venezuelan fisheries in 1972, when boats started dragging for scallops off northern Isla de Margarita and along the northern coast of Sucre State, in response to increased demand for scallops from the United States. The stocks do not appear to be overexploited in spite of the intensive fishing (Freddy Arocha, Fisheries Department of Instituto Oceanográfico de Venezuela, pers. comm.).

Amusium laurenti and *Argopecten nucleus* are captured by shrimp trawl in the northeastern and central parts of Venezuela, especially in the Golfo de Venezuela, but the landings are small and not recorded. Although *Euvola ziczac* and *Nodipecten nodosus* are the largest scallops in Venezuela, their densities are too small to support an organised fishery. They are only captured by individuals for local consumption, and occasionally appear in shrimp trawls.

Figure 28.4. The number of metric tons of the scallop *Amusium papyraceum* landed in northeastern Venezuela between 1970 and 2000 (Data from J. Alió, Instituto Nacional de Investigaciones Agropecuarias, Sucre–Nueva Esparta, Venezuela).

28.4 AQUACULTURE

The large size of the adductor muscle of *Euvola ziczac* and *Nodipecten nodosus* suggests that they should be good species for aquaculture and a number of studies have evaluated their growth and survival in suspended and bottom culture. In addition, one study has examined growth of the smaller scallop *Argopecten nodosus* in suspended culture.

28.4.1 *Euvola ziczac*

28.4.1.1 Gonad maturation and spawning

Laboratory studies by Vélez et al. (1993) suggest that during periods of gonadal growth in the field, between February and July, maturation can be induced by exposing scallops in the laboratory to temperatures 3–4°C above those in the natural beds. Alternatively, maturation can be stimulated by placing scallops in small bays where temperatures are naturally warmer. Once the gonads are mature, release of male and female gametes can be induced using an abrupt temperature increase, from 20 to 29°C (Vélez et al. 1990). Mature scallops do not release gametes when injected with serotonin, and only male gametes are released when scallops are subjected to both serotonin injections and abrupt temperature increases (Vélez et al. 1990).

28.4.1.2 Spat production

As the numbers of *E. ziczac* spat settling on collectors is low in the Golfo de Cariaco (the monthly rate is <5 spat per 30 x 60 cm onion bag filled with mono-filament netting), natural spat collection is insufficient to supply commercial culture (Lodeiros et al. 1997). Thus, hatchery production of spat is required. The existing studies of larval development of *E. ziczac* have focused on evaluating the nutritional value of several microalgal diets and in determining optimal food rations, larval culture densities and water temperatures. The best growth and survival is obtained at 27°C with a diet of *Chaetoceros gracilis* and *Isochrysis aff galbana* (T-ISO) at a density of 30,000 cells mL⁻¹ (Rojas et al. 1988). The density of larvae is initially maintained at 10 larvae mL⁻¹, later reduced to five larvae mL⁻¹ and finally to three larvae mL⁻¹. In the laboratory, where the above studies were done, the water was filtered and treated with ultraviolet light to reduce the abundance of organic particles, competitors, predators and pathogenic microorganisms. It is important to control the growth of pathogenic bacteria, such as *Vibrio anguillarum*, *V. alginolyticus* and *Pseudomona* sp. (Lodeiros et al. 1992; Freitas et al. 1993). When the above variables are adequately controlled, the larvae settle in 10 to 12 d with a survival rate of >50%. Settlement is greatest on the upper surfaces of roughened plexiglass collectors (angles from 0 to 45°) and when the water is maintained in motion (Vélez and Freitas 1993).

A major factor in producing spat is the cost of growing phytoplanktonic food for the postlarvae. Vélez and Ortega (1988) studied the feasibility of producing microalgae in outside basins, using agricultural fertilisers as the source of nutrients and the sun as the

source of light. Trials with *Tetraselmis chuii*, *T. suecica* and *Nannochloris oculata* produced favourable results. However, these species do not promote rapid growth of *E. ziczac* post-larvae. Slow larval growth increases costs because of the postlarvae must be manipulated more often and greater supplies of high quality water are needed. Vélez and Ortega (1988) could not reliably produce high quality diets, such as *Chaetoceros gracilis* and *Isochrysis aff galbana* (species characteristic of cooler regions). We have recently isolated two species of Venezuelan microalgae of the genus *Chaetoceros* and *Tetraselmis* that have been a good diet for culturing the larvae of several marine invertebrates, such as *Brachionus plicatilis* and *Litopenaeus vannamei*, but which we have not yet been tried as a diet for *E. ziczac* and other bivalves larvae and seed. Once *E. ziczac* spat attain 2 mm in shell length they are readily grown to 6 mm within 15 d (with >90% survival) in small 1-mm mesh lantern nets suspended in the sea (unpublished data). They can then be transferred to 3-mm mesh pearl nets.

28.4.1.3 Grow-out

The first study examining growth of *E. ziczac* in suspended culture showed a rapid increase in length during the first four month (from 3.3 to 44 mm) and then growth slowed coincident the an increase in gonadal size (Lodeiros and Himmelman 1994). A projection of the growth curve suggested it would take >3 years to attain the size generally found on natural beds (70–80 mm). We subsequently compared growth in three situations, (1) in cages suspended from a long line, (2) in cages at the same depth but placed on the bottom and (3) in partly buried cages at the same depth. The latter permitted the scallops to recess into the sand as they do in natural habitats. Shell and tissue growth was markedly greater in the partly buried cages than in the cages in suspension and on the bottom (A projection of the shell length curve indicated it would take about 1.5 years to attain the size on natural beds.). Further, survival was greatest in the partly buried cages (in the other treatments mortality may have been caused by organisms colonising the scallop shells). We hypothesised that *E. ziczac* grew better in the partly buried cages (1) because this scallop is better adapted to feeding on organic material at the sediment-water interface, or (2) because it is stressed when it cannot bury itself. A 5-month study evaluating the first hypothesis confirmed the greater growth in partly buried cages, and also showed an increase in the energetic content of sestonic food at the sediment/water interface compared to in suspension (Hunauld et al., in press). However, this difference could at most account for one third of the increase in growth in the partly buried cages.

In concurrent studies, Lodeiros and Himmelman (2000) ran four growth trials (starting with 10-mm scallops) to further evaluate factors determining growth and survival in suspended culture. Three trials followed growth of a cohort from spawning in August 1992, which was grown at three depths, 8, 21 and 34 m. The fourth trial used an April 1993 cohort, which was grown at 21 m. An exhaustive list of environmental variables was monitored during these growth trials (including physical and chemical factors, sestonic factors in two size fractions and fouling). Application of the stepwise multiple regression procedure to all trials together indicated that shell fouling was the main factor predicting somatic growth, and its affect was negative. Also, adding gonadal presence or

absence as a “dummy” variable showed that gonadal production negatively affected somatic growth (Somatic tissue growth stopped or slowed at the initiation of gonadal development in the three trials with the 1992 cohort). Likely the strong effects of fouling and gonadal production masked the influence of the other environmental factors. This was indicated by analyses applied separately to the different growth trials that showed that phytoplankton abundance was a good predictor of growth in the two fastest growing trials and temperature variability negatively affected growth in the two slow-growing trials. The variations in food availability and physiochemical conditions in the Golfo de Cariaco did not appear to limit the growth of juveniles (as no environmental factors predicted the tissue increases in juveniles). The growth of the April 1993 cohort suspended at 21 m was higher than that observed by Vélez et al. (1995) for scallops in partly buried cages. In both cases there was low shell fouling. The rapid growth of the April 1993 cohort contradicted our previous hypothesis that *E. ziczac* is stressed when maintained in suspended culture.

A 32 day experiment (too short to be affected by fouling organisms) examining the relationship between RNA/DNA ratios and growth for three size groups of *E. ziczac* maintained in suspension at 8, 21 and 34 m in depth further indicated that food availability is a major factor determining growth (Lodeiros et al. 1996). Juvenile (without gonads) and maturing scallops (with developing gonads) showed a decrease in growth with depth and fully mature individuals (with full-sized gonads) showed a decrease in reserves with increasing depth (Fig. 28.5). The decrease in growth with depth was correlated with seston quality, as indicated by the decrease in chlorophyll-*a* values and the energy content of the seston with depth (temperature only decreased by $\sim 1.3^{\circ}\text{C}$ with depth).

The negative effect of fouling was examined further using an experimental design, which permitted separating the effects of fouling on the pearl nets and on the scallops shells (Lodeiros and Himmelman 1996). Growth was least when there was both net and shell fouling. Growth in shell dimensions and mass were strongly affected by organisms colonising the pearl nets and only weakly affected by organisms colonising the shells. Fouling organisms on the shells only slightly affected growth in tissue mass but probably accounted for increased mortality. The mass of organisms growing on the upper valve was much greater than in the longer-term growth trials of Lodeiros and Himmelman (1996) and could have impeded the ability of the ligament to open the valves.

The rapid growth of *Euvola ziczac* under good conditions (e.g., April 1993 cohort and partly buried cages in 1992) shows that commercial-sized scallops (>50 mm) can be produced in 10 months (Lodeiros and Himmelman 2000). Growth of juveniles in suspended culture is rapid and seems little affected by environmental conditions, including fouling. Grow trials in pearl nets by Freites et al. (1993), starting with 9.6-mm juveniles, indicate that a good culture density would be 800 individuals m^{-2} up to a length of 25 mm, 200 individuals m^{-2} until the scallops attain 40 mm, and 100 individuals m^{-2} for larger sizes. As the growth of somatic tissues markedly slows with the onset of gonadal production (Lodeiros and Himmelman 2000), techniques for preventing gonadal development (e.g., producing triploids) or delaying gonadal development (e.g., moving the scallops to greater depths) could be used to extend the rapid growth phase. Once the scallops reach 30–40 mm in shell length, steps need to be taken to limit fouling. Nets

Figure 28.5. Mean of shell height and dry mass of muscle and remaining of tissues of *Euvola ziczac*, at the beginning of the study (initial size) compared to values after 32 days of culture at 8, 21 and 34 m in depth in the Golfo de Cariaco. Values sharing the same letter within each group are not significantly different, Scheffé test, $P > 0.05$).

need to be changed periodically. Greater culture depths would both reduce fouling and retard gonadal development.

Bottom culture after 30–40 mm, in enclosures that permit the scallops to bury themselves, would eliminate the negative effects of fouling and not diminish growth. Freites et al. (2000b) compared three bottom culture techniques, (1) cages without bottoms, (2) corrals, and (3) being placed freely on the bottom. In all three treatments, the scallops were set out at a density of 15 individuals m^{-2} on a sandy bottom (1 m^2 areas). The high dispersion rate in the third treatment (12 scallops m^{-2} disappeared in the first month) prevented comparisons with the other treatments. In the corrals, the escape rate increased progressively with time, from 1 to 5 scallops $\text{m}^{-2} \text{ month}^{-1}$, likely due to increased swimming ability with increasing size. In the treatment with cages, no scallops escaped, but survival was less than in the corrals (even when escaped scallops were counted as not surviving). This indicated that corrals were a better culture method than cages. Bottom culture density could likely be higher than 15 individuals m^{-2} , as we observed no differences in growth trials in corrals at 15, 35 and 70 individuals m^{-2} (unpublished data, this growth trial was during a period of high primary productivity).

28.4.2 *Nodipecten nodosus*

28.4.2.1 Gonad maturation and spawning

Gonadal growth and active gametogenesis occur at temperatures of 26 to 28°C during the principal period of reproduction from August to November (Vélez et al. 1987). Between February and July, gonadal growth is occurring in the field and maturation can be induced in the laboratory by maintaining the scallops at 7 to 8°C above the field temperature and providing them with phytoplanktonic food. Once the gonads are mature, spawning can be introduced by an abrupt temperature increase from 21 to 28°C (De La Roche et al. 2002).

28.4.2.2 Spat production

As for *E. ziczac*, hatchery production of spat will also be required for *N. nodosus* in the Golfo de Cariaco, because of the low numbers of spat settling on collectors (monthly rate of <5 spat per 30 x 60 cm onion bag filled with mono-filament netting, Lodeiros et al. 1997). We have cultured larvae and postlarvae using the same conditions (diet, food ration, density, temperature, water-changing schedule) as described above for *E. ziczac* and obtained larvae with an eyespot after 8 days and the post-larval dissoconch after 13 days (Vélez and Freites 1993). This compares with 11 and 14 days for the larval eyespot as observed for *N. nodosus* by De La Roche et al. (2002) and Marín (1994), respectively.

28.4.2.3 Grow-out

The first grow-out trials with *N. nodosus* by Lodeiros et al. (1998) were made in pearl nets suspended at 8, 21 and 34 m in depth at Turpialito, and started with scallops measuring

9.4 mm in shell height. The growth rate of the shell and somatic tissues decreased progressively with depth (Fig. 28.6) and appeared to be explained by food availability, as phytoplankton biomass decreased proportionally with depth (and temperature only decreased slightly with depth). Muscle mass attained 5–6 g after 5 months and at this size could be sold commercially. Mortality was low throughout the study at 21 m, whereas at 8 m major losses occurred after 6 months that appeared to be due to heavy shell fouling. The reduced growth rate, low survival and near lack of gonadal development at 34 m indicates that conditions at this depth are unfavourable for *N. nodosus*. We subsequently quantified the biochemical constituents of the major body components of *N. nodosus* for the scallops in the above experiment (Lodeiros et al. 2001). Protein in the digestive gland, and carbohydrates in the muscle and remaining somatic tissues, dropped during maximal gonadal growth suggesting transfer of nutrients from these tissues to gonadal production. Further, the greater use of lipids in the digestive gland during the reproductive period for individuals at 21 m than at 8 m was possibly because phytoplanktonic food was less abundant at 21 m. When conditions were likely stressful (low food availability, high temperatures, colonisation of fouling organisms and exhaustion from reproduction), protein levels in the remaining somatic tissues decreased and lipid levels stabilised.

Acosta et al. (2000) ran intermediate growth trials at 8 m in depth, starting with 9.4 mm juvenile *N. nodosus*, to examine the effect of culture density on growth and survival (6 densities: 7, 15, 30, 60, 125 and 250 scallops/pearl net). They show that increasing density decreases growth but not survival and recommend a schedule for reducing densities that should permit producing 50 mm scallops (ready for final growout) in 6 months.

Freites et al. (2001) compared three bottom culture methods for final growout (starting with 34 mm *N. nodosus*), (1) in corrals, (2) in pockets attached to an anchored line, and (3) in anchored sleeves. Survival was similar for the three methods, but all body components showed that growth was greatest in corrals and least in sleeves. The increased growth in the corrals was possibly because the scallops bysally attached to the corral walls so that they had greater access to suspended food particles (or to better quality particles), as for scallops in suspended culture. Finally, Mendoza et al. (2003) compared growth and survival of scallops, measuring 40 mm in shell length, maintained in four types of enclosures, in sacs, cones and lantern nets suspended at 6 m in depth, and in 1 x 1 m corrals set up at 6 m in depth on the bottom. The scallops covered about a third of the bottom for each treatment. The increase in tissue growth during the 4.5-month study was 36 to 48% greater in the suspended culture enclosures than in the bottom corrals and cumulative mortality was greater in the bottom corrals (45%) than in suspended culture treatments. There were no significant differences between lantern nets (33%), sacs (22%) and cones (20%). In contrast to the previous study by Lodeiros et al. (1998), this study did not show a negative effect of fouling, even though the study lasted for 4.5 months.

Figure 28.6. Changes in shell height and dry mass of the muscle, digestive gland, and remaining somatic tissues of the scallop *Nodipecten nodosus* maintained from December 1993 to October 1994 in suspended culture at 8, 21 and 34 m in depth at Turpialito, Golfo de Cariaco, Venezuela. Vertical bars represent 95% confidence intervals.

28.4.3 *Argopecten nucleus*

The numbers of natural spat settling onto onion bags filled with mono-filament netting is greater for *A. nucleus* than for *E. ziczac* and *N. nodosus* (monthly rate of ~20 spat per 30 x 60 cm onion bag; Lodeiros et al. 1997). Nevertheless, hatchery production will be needed to support commercial production.

The one growth study of *A. nucleus* (Lodeiros et al. 1993) started with individuals measuring 10 mm in shell length (~1.5 months in age), which were maintained in suspended pearl nets at 15–20 m in depth. The scallops attained 45–50 mm in length (approaching maximum size), with the adductor muscle weighing about 0.8 g in dry mass (3–4 g in wet mass), 6–7 months later (Fig. 28.7). At this size they could be sold commercially, either the muscle alone or all tissues together. This growth rate exceeds that reported for *Argopecten irradians* in North Carolina and *A. gibbus* in Florida. *Argopecten nucleus* appears to be suitable for suspended culture because it tends to resist colonisation by fouling organisms (at least when individuals are transferred to new pearl nets after the 1st and 6th month of culture, at the same time as reducing densities.

Figure 28.7. Mean of shell length and dry mass of tissues of *Argopecten nucleus* maintained in pearl nets at Turpialito, Golfo de Cariaco, Venezuela. Vertical bars indicate 95% confidence intervals.

28.5 PERSPECTIVES FOR CULTURE

For *Euvola ziczac* and *Nodipecten nodosus*, the low numbers of juveniles in natural beds and the low numbers of spat recruiting on suspended structures, as noted at Turpialito, indicates that commercial culture of these scallops will require the development of cost-effective hatchery techniques. As stated above, hatchery methods also need to be developed for *Argopecten nucleus*. It will likely be advantageous to grow the post larvae using natural sources of phytoplankton as early as possible. For *E. ziczac*, we have had >95% survival when growing 2 mm spat in suspended culture for 15 days (unpublished data).

The rapid growth and short life span of *A. nucleus* means that this scallop can be cultured in <9 months. Production of this scallop can likely be increased by varying culture depth and the type of enclosure employed. Growth trials need to be made starting in different seasons. Using a combination of suspended and bottom culture, it should be possible to produce commercial-sized *E. ziczac* (70–80 mm in length) and *N. nodosus* (80–90 mm) in 12 to 15 months. The culture will involve a first period of suspended culture (up to 30–40 mm in length for *E. ziczac* and to a larger size for *N. nodosus*), as the small individuals are easily handled, tend to be little colonised by fouling organisms, and have high rates of growth and survival. Both species tolerate relative high culture densities (Campos 1991; Freitas et al. 1995; Acosta et al. 2000, unpublished data). The data available on the growth rates related to culture depth and density provide a good basis for developing a suspended culture strategy.

Although rapid growth rates provide a distinct advantage for suspended culture of scallops in the Golfo de Cariaco, and probably in many tropical regions, two factors, that may be specific to tropical regions, will limit production and increase costs. The first is fouling. A large variety of organisms, notably barnacles, anemones, other bivalves (e.g., oysters and pearl oysters), bryozoans, and tube forming amphipods and polychaetes, can colonise and grow profusely on scallops and suspended structures. Our growth trials document decreased rates of growth and survival of *E. ziczac* coincident with increases in fouling (Lodeiros and Himmelman 1994, 1996, 2000; Vélez et al. 1995; Freitas et al. 1996). Inversely, prolonged rapid growth of *E. ziczac* (equivalent to that in bottom culture where the burying behaviour of the scallops prevents fouling) was observed in the one growth trial during a period when there was little colonisation by fouling organisms (August 1993 cohort, Lodeiros and Himmelman 2000). Fouling organisms may negatively affect production in suspended culture by reducing the flow of food particles to the scallops, by directly competing for food particles, and by encrusting the scallop shells so as to interfere with opening and closing of the valves. Mortality is most likely attributed to organisms colonising the shells (Lodeiros and Himmelman 1996). Fouling organisms will also decrease profitability by greatly adding to the costs of maintaining culture lines and enclosures in suspension. *N. nodosus* is much more resistant to fouling than *E. ziczac* (Lodeiros et al. 1998; Mendoza et al. 2003; Freitas and Nuñez 2001). Nevertheless, Lodeiros et al. (1998) noted mortality and decreased growth coincident with heaving fouling in individuals grow in shallow water (8 m). In this case, the dry mass of fouling organisms on some dead scallops exceeded the mass of the shell.

The second factor that could limit suspension culture of scallops in Venezuela is the impact of predation by invertebrates settling on the suspended culture enclosures. Freites et al. (2000a) found that six carnivores (crabs and gastropods) that recruited onto pearl nets that had been immersed during 2 months (mid February to mid April 1994) caused significant mortality when subsequently added to pearl nets stocked with 25 *E. ziczac* (32 mm in shell length). One individual gastropod *Cymatium poulsoni* or crab *Pilumnus caribbaeus* (both species settled onto about half of the pearl nets) killed 22–25 of the scallops in 30 days. Together, these predators could cause 50% mortality in pearl nets stocked with 25 scallops in 6 days.

Appropriate steps, such as periodically transferring the bivalves to new enclosures, removing predators from enclosures every 15 days (mainly during the first 2–3 months) or developing biological controls of predators, will be needed to limit predation losses but will add to production costs. Later, recruiting predators should be removed at about 2-month intervals, thus before they attain a size where they can attack the scallops. This may be achieved at the same time as changing nets to reduce fouling. The culture strategy should be flexible and involve monitoring fouling organisms and predators to determine when control measures are needed.

Finally, a third factor that is critical in producing *E. ziczac* in suspended culture is the effect of wave action. Freites et al. (1999) demonstrated that the survival and growth rates of all body components are markedly reduced when scallops are maintained in enclosures that move about by wave action. The smooth convex lower shell and lack of byssal attachment, causes *E. ziczac* to readily slide around in suspended enclosures, and this causes damage to the shell and mantle edge. Thus, *E. ziczac* must be cultured in enclosures that are suspended in a way so that wave action is not transmitted from surface buoys, or be cultured in protected sites (if this does not reduce the carrying capacity of the enclosures). In contrast to *E. ziczac*, *N. nodosus* is not negatively affected by wave action because it bysally attaches to the sides of enclosures (Freites et al. 1999). This may also be the case for *A. nucleus* since it attaches bysally.

After a certain size, bottom culture will likely be a more appropriate culture strategy for both *E. ziczac* (at 30–40 mm) and *N. nodosus* (at 50–70 mm). Adult *E. ziczac* show high growth rates in bottom culture if the culture method permits the scallops to bury themselves as in natural beds (Vélez et al. 1995; Hunauld et al., in press). Whereas growth rates of adult *N. nodosus* are less in bottom than suspended culture, bottom culture may nevertheless be advantageous because of reduced equipment and maintenance costs. Seeding of the bottom needs to be explored as a culture technique for both scallops. Studies are particularly needed to evaluate losses due to predation and dispersion. Dispersion may be limited for *N. nodosus* because it attaches bysally and is not a good swimmer (especially individuals measuring >50 mm in shell length). Experimental studies should first be done at a small scale and then extended to trials at a large enough scale to mimic a commercial operation. There is likely a size at which losses from predation and dispersion decrease, and this size should be optimal for bottom seeding. Future studies should involve an economic analysis to evaluate the factors affecting profitability of different culture methods and to identify the research directions most likely

to aid in establishing culture operations. An economic analysis could also be used to choose the optimal size for harvesting the scallops.

Chapter 29

Mexico

Esteban Fernando Félix-Pico

29.1 FISHERY

29.1.1 Introduction

Scallops are an important fishery and under intensive exploitation in México. Commercial fishing activity began in the Gulf of California in 1970, and at the end of the 1980's annual landings averaged about 32,000 t. The scallop fishery is notoriously variable, so by 1991 to 1995 landings had declined to about 900 t. This decline has served as an impetus for fishery enhancement through aquaculture. The State of Baja California Sur is the production leader with more than 95% of the Mexican production (Félix-Pico 1991a, b).

The Mexican species have been assigned new scientific names. Almeja Catarina or Pacific Calico Scallop (Poutiers 1995) was named *Argopecten circularis* (Sowerby I, 1835), but is now known as *Argopecten ventricosus* (Sowerby II, 1842) because the holotype was misidentified (Waller 1991, 1995). The Mexican lion's paw was known as *Lyropecten (Nodipecten) subnodosus*, but was replaced by *Nodipecten subnodosus* (Sowerby I, 1835) because the genus *Lyropecten* is extinct in the Pacific Ocean (Smith 1991). The Voladora scallop has been renamed from *Pecten (Oppenheimerpecten) vogdesi* to *Euvola vogdesi* Arnold, 1906; reviewed by Waller (1991). These species are listed in order of their importance to the fishery. Pectinids are among the most attractive of all bivalves, both in shape and colours, and they have been used as the emblem of the shield of the State of Baja California Sur. Scallops inhabit only shallow tropical and subtropical Eastern Pacific waters, including the Gulf of California. The commercial fishing area for each species shows the geographic distribution of fishing and aquaculture (Fig. 29.1). As fisheries have developed, particularly over the last three decades, researchers and fishermen have discovered much about the species inhabiting Mexican waters; their basic biology, habits, physiology, ecology, genetics (for use in aquaculture) and sustainable production potential. More than 100 scientific papers have been published in the last 10 years on these subjects.

Currently, experimental and commercial efforts to develop further the aquaculture of scallops in México are being made by Secretaría del Medio Ambiente Recursos Naturales y Pesca (SEMARNAP), Centro Interdisciplinario de Ciencias Marinas (CICIMAR), Centro de Investigaciones Biológicas del Noroeste (CIBNOR), Universidad Autónoma de Baja California Sur (UABCS), Universidad Autónoma de Baja California (UABC),

29.1.2 Species and Distribution of Scallops

Scientific name: *Argopecten ventricosus* (Sowerby II, 1842)

Common names: Almeja Catarina (México), Conchuela (Panamá), Pacific Calico scallop (FAO).

Mexican species code: 0281428H.

Diagnostic features: Solid medium to large shell, very inflated form, with both valves convex, sturdy shells, strongly ribbed with about 21 ribs (17 to 22 each valve), anterior and posterior ears about equal in size, raised concentric growth lines in spaces between ribs. A wide variety of colour and marking is seen, from almost pure white through blotched and streaked patterns to solid dark orange and brown or purple (Keen

1971; Keen and Coan 1974; Poutiers 1995). Usually has internally a wide chocolate-brown band or whitish background, varying in width and intensity and is similar in appearance to its twin species from the Gulf of México, *Argopecten gibbus*. Length is about 60 mm (maximum size 81 mm). Whole weight about 70 g and adductor muscle 8 g.

Distribution: From Isla Cedros, Baja California, through the Gulf of California and southern México to Paita, Perú. The northern subspecies, *A. ventricosus aequisulcatus* (Carpenter, 1864), ranges from Santa Barbara, California, USA, to Baja California Sur (Bahía de La Paz and Bahía Magdalena) (Poutiers 1995).

Scientific name: *Nodipecten subnodosus* (Sowerby I, 1835)

Common names: Almeja Garra or mano de león (México), Pacific lion's paw scallop (FAO).

Mexican species code: 0241026H

Diagnostic features: The largest and heaviest of the West American tropical species, grows to 170 mm. Thick, solid, convex equivalve and fan-shaped, 10 to 11 ribs are very conspicuous, some of them with large knobs or nodules, which makes the species easy to recognise (Rombouts 1991). Shell sturdy in texture, valves strongly convex, shell heavy, ribs subdivided by small, overlying riblets. Colours ranging from dull purple or white with purple lines to brilliant shades of orange and magenta. A similar species is *Nodipecten nodosus* (Linnaeus, 1758), from the Atlantic, more nodose and with one less rib (Keen 1971). Length about 175 mm (maximum size 218 mm), diameter about 75 mm. Whole weight is about 1,400 g and adductor muscle 160 g.

Distribution: From Laguna Ojo de Liebre (Guerrero Negro), Baja California Sur, through the Gulf of California and southern México to Perú.

Scientific name: *Euvola vogdesi* Arnold, 1906

Common names: Almeja Voladora (México), Vogde's scallop (FAO).

Mexican species code: 0401422H

Diagnostic features: Medium to large, strong shell. Right valve convex with about 21 (20–22) ribs, rounded ribs, left valve flat or slightly concave with about 20 ribs, darker colour, from buff to bright reddish brown, brighter on left valve, interior white to pinkish brown (Keen 1971; Rombouts 1991). Ears nearly equal in size, byssal notch small, ribs strong, smooth. Primarily a tropical genus, one species occurs in México. Length and height about 100 mm. Whole weight about 115 g and adductor muscle 12 g.

Distribution: From Punta Eugenia, Baja California Sur, through the Gulf of California and south at least to Panamá.

29.1.3 History of the Fishery

This fishery has been sustained by private investment authorised by the SEMARNAP, México. After the abalone fishery, the pectinid fisheries have been the most important economic factor in Baja California shellfish during the last decade. Within nine years (1989–1997), national scallop production rose from 1,000 t to over 32,000 t year⁻¹, caused entirely by the control and administration of the seabed stock. Scallop diving has become

an efficient and well-organised form of fishing, and encouragement of scallop diving can help conserve an important natural resource for future harvests because the diver sees scallops in their natural surrounding and his observations can contribute to a better understanding of their habits and life cycle.

The Peninsula of Baja California is where the main exploitation grounds and culture areas are to be found (Fig. 29.1). They are Bahía de Los Angeles in Baja California, Lagunas Ojo de Liebre, Guerrero Negro, and San Ignacio, and Bahías Magdalena, Concepción, and de La Paz in Baja California Sur, and Bahía de Bacochibampo in Sonora, on the Gulf of California. It is difficult to obtain accurate data of landings in the official Mexican Sea Fishery statistical tables before the early 1970's, because before that landings of voladora and catarina scallops were so small they were included with other shellfish. Data for both species were combined until the 1970's. The information in the Mexican Annual Fishery Statistics (captured production) has tables named "Almeja". Although the term "Almeja" means "clam", it is normally used to refer to all bivalves, including all species of scallops, arks, clams and pens (SEMARNAP 1999).

At the beginning, in the 1970's, scallops were collected by divers operating from boats using hookah gear, the same equipment now still used. Dredges were never used. At each fishing ground, 50 to more than 800 boats worked.

The fishery of Bahía de los Angeles, Baja California collapsed suddenly after 4 years of intensive harvest. The fishery peaked in 1972, when about 4,400 t were landed in Bahía de Los Angeles and Punta San Bruno, Baja California Sur. The fishery of Bahía de La Paz peaked in 1973, with about 90 t landed. These beds were the first exploited on a commercial scale and the fishery expanded rapidly. In 1975, a fishery started at Bahía Magdalena and Laguna San Ignacio, but they have never reached the size of the Gulf fisheries. Between 1976 to 1980, there was a radical change in the fishery, with the catch falling in 1977 to only 20 t. As the fishery expanded the number of boats increased. The number of fishing boats had risen to more than 92 for each fishing season. In 1983, scallop landings reached 2,500 t (value \$3.2 million US dollars). The discovery of a lucrative market in the United States of America caused the major part of the production to be exported. In 1990, scallop landings reached more than 30,000 t, with the number of fishing boats increased to 871.

29.1.4 Status of the Resource

29.1.4.1 Reproductive biology

29.1.4.1.1 Size at maturity

Argopecten ventricosus is a functional hermaphrodite and generally protandrous (Villalaz 1994) with two spawning periods during the year. The gonad is cream coloured in the male portion and orange reddish to vermilion in the female portion (Tripp-Quezada 1991; Félix-Pico et al. 1995). Catarina scallops reach sexual maturity at 8 months to one year. The minimum size at sexual maturity is approximately 30 mm (Baquero et al. 1981) or 35 mm (Villalejo-Fuerte and Ochoa Baez 1993).

Nodipecten subnodosus and *Euvola vogdesi* are also functional (Carvajal-Rascón 1987; Ruiz-Verdugo and Cáceres-Martínez 1991; Gutiérrez Villaseñor and Chee Barragán 1997). Under natural conditions, *N. subnodosus* is mature at one year or more, when the organism is approximately 80 mm for the male and 93 mm for the female (Reinecke 1981).

29.1.4.1.2 Fecundity

Argopecten ventricosus: Fecundity increases with shell height, but sizes between 58 and 77 mm have maximum reproductive potential (Fig. 29.2) (Villalejo-Fuerte and Ochoa-Baez 1993). The mean fecundity was calculated by regression analysis during spawning in February-March (12 million oocytes). Using a sample of 101 individuals gave by the equation:

$$Y = 0.662 X^4 \text{ with } r = 0.70 \quad (1)$$

At the end of the reproductive season (Villalejo-Fuerte 1995), the relationship was described by the equation:

$$Y = 1.057 X + 146,000 \text{ with } r = 0.1 \quad (2)$$

Under laboratory conditions, when scallops have been stimulated, spawning fecundity varied between 2 and 3 million oocytes per 45 mm shell height. For the male portion, there were an estimated 100 to 250 million spermatocysts (Monsalvo-Spencer 1998).

29.1.4.1.3 Maturity and spawning

Argopecten ventricosus: Spontaneous natural spawning occurs throughout the year, indicating there are at least some ripe individuals in the population at all times. Baqueiro and Arana (2000) studied the reproductive cycle in Ensenada de La Paz (Golfo de California), reporting three high intensity spawning periods with 30% in February, 90% in June, and 70% during August. Cáceres-Martínez et al. (1990) determined, by gonadic index from Bahía de La Paz, two intense gonadal activities between February-March and September-October. Luna-González et al. (2000) reported, also for Bahía de La Paz, ripe stages throughout the year were present in February to May, July-August (maximum 50%), and October to December. The resting stage was seen only in June and September (47 to 91%). The spent gonadal stage may be partial or complete. It has a flabby appearance of dull orange and the testis is yellowish white.

The reproductive season of *Argopecten ventricosus* in Bahía Magdalena is slightly different than that of the Gulf coastal lagoons. Tripp-Quezada (1991) reported that in northern Bahía Magdalena (Estero Sto. Domingo), spawning occurs sooner than in Bahía Concepción. There was a massive spawning from January to March and between October and November. Félix-Pico et al. (1995) determined two major spawnings a year, during April-May and in August in central Bahía Magdalena.

Figure 29.2. Relationship between shell height and potential fecundity in *Argopecten ventricosus*. Estimated by the equation No. 1. (From Villalejo-Fuerte and Ochoa Baez 1993).

Spawning intensity can be correlated with water temperatures. In central Bahía Magdalena, spawning occurs (March-April) when the bottom temperature reaches 15°C to 17.5°C, at about 20-m depth (Félix-Pico et al. 1995). In northern Bahía Magdalena, spawning occurs when temperature drops from 30°C to 22°C, with a minimum value of 19°C in January (Tripp-Quezada 1991). Villalejo-Fuerte and Ochoa-Baez (1993) reported that in Bahía Concepción the highest frequencies of mature scallop were caused by decreasing the temperature from 30°C to 21°C during autumn. The spawning season began in January, when the water temperature was decreasing, and that maximum spawning coincided with lowest temperature (16°C) recorded during the annual cycle, and continued until April, when water temperature began to increase. Reproduction occurred after a process of energy transfer from the adductor muscle to the gonad. This was attributed to the seasonal fall of temperature, which had a favourable influence for the energy transfer used in gametogenic development and spawning (Villalejo-Fuerte and Ceballos-Vázquez 1996).

For Ensenada de La Paz, scallops spawn from late February to March when the water temperature rises from 19°C to 21°C (Félix-Pico et al. 1989). Cáceres-Martínez et al.

(1990) determined ripe gonads are associated with a decrease in temperature from 31°C to 26°C in Bahía de La Paz.

Lora-Vilchis et al. (1997) studied the physiological mechanisms for spawning process control. When the sperm is ejected, the female part of the gonad begins to show the following changes. The nucleolus begins to disappear as do the endoplasmic reticulum and the Balbiani complex. Sperm emission usually begins before oocyte emission. Muscle fibres inside the gonad probably contribute to the spawning process. Avilés-Quevedo (1990) observed total evacuations of gametes under laboratory conditions and also indicated spermatozooids are released before the ovules.

Other exogenous factors have been related to the spawning of *A. ventricosus* in natural conditions. Baqueiro-Cárdenas and Aldana-Aranda (2000) associated a spawning period in June to a change in salinity, from 34.5‰ to 38‰, but Luna-González et al. (2000) found the salinity does not affect the reproductive cycle. Félix-Pico et al. (1989) mentioned that spawning is directly related to the lunar phases and it occurs during the full moon. In Bahía Concepción, Villalejo-Fuerte and Ochoa-Baez (1993) believed the proportion of mature scallops in relation to the photoperiod suggests the synchronisation of gametogenic development and maturity through an undescribed neuroendocrine component.

The gonadosomatic index is not a good indicator of the reproductive cycle because the gonads tend to accumulate water when they are in the resting stage Luna-González et al. (2000). But other authors have reported that the index is a good indicator because reproduction was believed to occur after a process of energy transfer from the adductor muscle to the reproductive system (Tripp-Quezada 1991; Villalejo-Fuerte and Ochoa-Baez 1993; Villalejo-Fuerte 1995; Villalejo-Fuerte and Ceballos-Vázquez 1996; Félix-Pico et al. 1989).

The influence of food, biochemical composition, and abundance of particles also must be considered. The phytoplankton community of Bahía Concepción was represented by diatoms (131 spp.), dominated by species of *Chaetoceros*, *Rhizosolenia* and *Nitzschia*. The carbohydrate/protein ratio and chlorophyll concentration were monitored during the cold season, and they have a better nutritional quality in terms of POM (Particulate Organic Matter) during the cold season (Verdugo-Díaz 1997). The inorganic seston/organic seston ratio (IS/OS ratio) influences the spawning stage, and with food and adductor muscle reserves, influences the developing and ripening of gametes. The IS/OS ratio had no clear relation to the reproductive cycle. Low quality and quantity of food in May led to the resting stage in June in Bahía de La Paz (Luna-González et al. 2000). In Bahía Concepción, Martínez-López and Garate-Lizárra (1994) reported an abundance of diatoms during the winter season (1994), related to maturity and spawning. This contribution of high-energy-content particles coincides with the maximum phytoplanktonic production cycle. This represents an important contribution of additional food, considerably reduced, that would cause a decline in production within the bay. These observations suggest that decreased food quantity may affect the catch of this scallop, which was low in 1994. On an interannual scale, in 1994 the particulate organic matter production decreased during a good part of the reproductive period of the catarina scallop (Palomares-García and Martínez-López 1997).

Nodipecten subnodosus: Under natural conditions *Nodipecten subnodosus*, spawning occurs when temperature decreased from 22°C to 17°C during October, with a maximum value of 84% for males and 56% for females (Reinecke 1981).

29.1.4.2 Population biology

The age composition of voladora and catarina scallop populations depend heavily on year-class strength. Because of the short life span of *Euvola vogdesi* and *Argopecten ventricosus*, age composition data generally show the presence of only two year-classes in the population. The nature of the fisheries is such that relative age composition data are not very important and hence largely unavailable. Age at first capture of catarina and voladora scallops is about 1 year, and for *Nodipecten subnodosus*, at least 2 years.

Size composition data for voladora and catarina scallop populations are scarce in the literature. Aguilar-Ruiz (1975) produced details of the size-frequency distribution of a population of *E. vogdesi* from Bahía de Los Angeles, Baja California. There was a compact size-group with a well defined modal peak at 72–81 mm length. The samples were collected in May 1971, and a unimodal year-class was present.

Yoshida-Yoshida and De Alba-Pérez (1977) collected samples of catarina scallop from Ensenada de La Paz, Baja California Sur, between May 1976 and May 1977. They demonstrated a bimodal distribution from May until July because of the presence of the two year-classes; the younger having been spawned in early spring. *A. ventricosus* has a distribution in the southern part of the Ensenada. There are distinct populations with similar size composition. The smallest individuals are 19–22 mm in length, the largest scallops are 51–69 mm, and the averages for the three separate populations are 44, 53 and 58 mm in length.

Baqueiro et al. (1981) continued with those studies in Ensenada de La Paz between December 1977 and August 1978. They demonstrated that the 0 and 1 (age-structure) groups are truly representative of their relative proportions in the population and found that groups are not unimodal; probably a result of the two spawnings in one year. They found evidence of a seasonal change in size composition. From March until June, there were no small (21–40 mm) catarina scallop in their samples, but in July small scallops constituted 5% to 8% of the total in the samples. In August, this increased to more than 60%, indicating the entry of another year-class into the fishery. The average length was between 51.5–57.7 mm in large scallops and 30 mm for small scallops. The population decreased because of overfishing and adverse environmental factors. This area is now closed to fishing.

Tripp-Quezada (1985) has monitored Bahía Magdalena at an eelgrass meadow in Estero Santo Domingo. The size at the first capture of the catarina scallop is about 42 mm (after the first spawning which takes place in the first half of the year), the average size is about 50 mm, and the maximum size is 63 mm. He also established condition factors and demonstrated the commercial size of 45 mm and the total weight of about 27 g.

León-Carballo et al. (1991) has evaluated Bahía Concepción and defined an adult population group between 51–71 mm with maximum concentrations between 55 and 63 mm. The average size was 59 mm for the catarina scallop.

Yoshida-Yoshida and De Alba-Pérez (1977) produced a length/weight relationship for *A. ventricosus* from Ensenada de La Paz. This relationship from a sample of 112 individuals gave:

$$Y = 0.78 X - 25.8 \text{ with } r = 0.56 \quad (3)$$

Tripp-Quezada (1985) produced total weight/visceral weight and visceral weight/adductor muscle weight relationships for catarina scallops from Santo Domingo. This first relationship for a sample with 75 individuals was:

$$Y = 0.964 X + 0.329 \text{ with } r = 0.98 \quad (4)$$

The second relationship can be described by the equation:

$$Y = 0.968 X + 0.096 \text{ with } r = 0.75 \quad (5)$$

These data represent proportional relationships of 1:1/4 and 1:1/3. Félix-Pico (1987) obtained a length/weight relationship for catarina scallop from the Bahía Concepción. This relationship for 151 individuals can be described by the equation:

$$W = 0.0024 L^{2.4} \text{ with } r = 0.67 \quad (6)$$

At the beginning of the season, the values are 58 mm and 40 g. In the last month of the season, we found low values between 46 mm and 50 mm with total weight 36 g. Félix-Pico (1993) has monitored central Bahía Magdalena at depths between 10 and 25 m. The size at the first capture of the catarina scallops was about 47 mm, the average size was about 56 mm, and the maximum size was 70 mm in height at the beginning of the fishing season. During April, the average size was 48 mm and in May the average size was 50 mm in height. In summer, the average size decreased from 54 to 51 mm and again increased in winter to 59 mm and 61 mm during December 1989 and January 1990.

The sampling site at Bahía Magdalena was assumed to represent monthly size increases during the 5 month period from April to August 1990 (Félix-Pico et al. 1994). The Ford-Walford method was used to estimate L_{∞} , the asymptotic shell height. A von Bertalanffy growth curve was fitted (Fig. 29.3) and the estimated parameters were $L_{\infty} = 71.6$, $K = 0.117$ (1.4 per year) and $t_0 = -6.23$, with age groups between 51 and 68 mm. The equation obtained was:

$$L_t = 71.63 [1 - e^{-0.1167(t + 6.2311)}] \quad (7)$$

29.1.4.3 Abundance and density

Félix-Pico (1991a) reported the densities of *A. ventricosus* in Ensenada de La Paz in August 1975 averaged 4 organisms m^{-2} and in November to December 1975, density averaged 10 individuals m^{-2} . Yoshida-Yoshida and De Alba-Pérez (1977) assessed the

Figure 29.3. Growth curve calculated by the equation No. 7, from data of the natural population in Bahía Magdalena. (From Félix Pico et al. (1994)).

density of catarina scallops on the same beds. The sampling method was by diving using a one square meter area and random sampling. The density estimated during May to July 1976 averaged 6 individuals m^{-2} . Baqueiro et al. (1981) reported the densities of catarina scallops also on the Ensenada de La Paz beds from December 1977 averaged 13 individuals m^{-2} and in March 1978 averaged 3 individuals m^{-2} . They also estimated biomass ranged 545 g m^{-2} and 125 g m^{-2} for the same dates. Average biomass production was 55 g m^{-2} month during this period, and reported 48 g produced during this period.

The study of population size of *Argopecten ventricosus* was made by León-Carballo et al. (1991) who estimated abundance of Bahía Concepción stocks in 1988. An estimated abundance of 61.7 million scallops was calculated, with 85% above the minimum size limit for commercial catch (56 mm). A total biomass of 385 t of adductor muscles with an exploitable potential of 213 t was also calculated.

The population density during 1989 and 1990 had a maximum value of 26 scallops m^2 in Bahía Magdalena, decreasing to 4 scallops m^{-2} in April 1990 at the end of the fishing season (Félix-Pico 1993). A total biomass of 2,880 t of adductor muscle was taken during 1989 and 2,820 t in 1990, which represents about 79% of total production.

An intensive capture of the scallop *Euvola vogdesi* was made (Pineda-Barrera and López-Salas 1972; Aguilar-Ruiz 1975). They estimated the standing crop of voladora scallop at Isla Angel de La Guarda (Puerto Refugio, northern part) to be about 4 million, and at the eastern part of the island (Cantiles) to be about 3 million. Aguilar-Ruiz (1975) reported the standing crop of voladora scallops in Bahía de Los Angeles to be about 2 million. From June to August 1972, in the area among San Marcos de Tierra, San Rafael, and the southeast of Isla San Marcos, B.C.S., a dense bank of this scallop was exploited to its maximum level (Holguin-Quifones 1997). In September 1972, Pineda-Barrera and López-Salas (1972) obtained densities of 16 and 26 organisms m^{-2} in an area of 2,240,000 m^2 at Isla Angel de la Guarda. At the end of summer, Holguin-Quifones (1997) in San Marcos, when the fishing activity was declining, obtained an average density of 5 organisms m^{-2} covering an area of 12 km^2 . Aguilar-Ruiz (1975) recorded densities of 15 and 16 organisms m^{-2} in two locations in Bahía de Los Angeles.

During 1989 and 1990, 750 million scallops were gathered at the mouth of Bahía Magdalena, at depths between 12 and 25 m, yielding 5,190 t of meat (Maeda-Martínez et al. 1993). Apparently exploited beds are formed only when temperatures are 16°C or lower deep inside the bay for at least 2 months. Leija-Tristán et al. (1996) estimated biomass of *A. ventricosus* varied from 11 $kg\ ha^{-1}$ (depth to 15 m) and 0.9 $kg\ ha^{-1}$ at greater depths (29 m deep). Capture of scallops over the continental shelf indicated that this species was associated with temperatures between 14°C and 15.9°C, with salinity approximately 35‰.

29.2 EXPLOITATION OF THE RESOURCE

29.2.1 Fishing Areas

The most important fished stocks of *Argopecten ventricosus* and *Euvola vogdesi* are along the coast of the Baja California Peninsula - notably along the Pacific coast. The fishing grounds for *Nodipecten subnodosus* are in Lagunas de Ojo de Liebre and Guerrero Negro. Figure 29.1 shows the main stocks of scallops around the Baja California Peninsula.

There are five important catarina scallop grounds inside the bays of Baja California Sur. The smaller grounds on the East Coast are in Bahía de La Paz (closed) and Bahía Concepción. The largest areas containing commercial concentrations of catarina scallops are Laguna de San Ignacio, Lagunas Ojo de Liebre-Guerrero Negro and Bahía Magdalena on the Pacific coast. These are between 28°N 114°W and 24°N 111°W on the west coast of the peninsula. The grounds in the Gulf of California are at approximately 26°N 110°W (Bahía Concepción) and 24°N 110°W (Ensenada de La Paz).

Extinct beds have been found of *E. vogdesi* in Bahía de Los Angeles and at Isla Angel de La Guarda in Baja California (29°N 113°W), and Punta San Bruno, San Rafael and Isla San Marcos (27°N 112°W) in Baja California Sur.

The fishing grounds of *Nodipecten subnodosus* are in Lagunas de Ojo de Liebre and Guerrero Negro at approximately 28°N 114°W.

Bay scallops, by the nature of their habitat, are not found concentrated in large grounds. The catarina scallop beds have been estimated to cover some 200 hectares, which are distributed in patches inside the bays. Nine fishing areas were marked off over 374 ha of distribution sites in Bahía Concepción (León-Carballo 1991). Eighteen fishing areas were located ranging from Estero Santo Domingo (Sta. Helena), Bahía Magdalena (Pto. San Carlos), Bahía Almejas (Pto. Chale), to Rancho Bueno. These grounds were evaluated in the 114,000 ha of distribution area in Bahía Magdalena (Félix-Pico 1993).

Bay scallops are harvested from shallow water between 6 m and 35 m and often 3 m or less in the tidal channels. The maximum depth range for catarina scallops in the open sea is 150 m (not commercial grounds) (Maeda-Martínez 1993; Leija-Tristán et al. 1996).

In the northern part of the península, beds of voladora scallop in Bahía de Los Angeles were 15 m to 40 m. These grounds occur <1 km from the coast. The mano de león scallop beds had a depth range of 6 m to 14 m inside channels.

The bottom of the catarina scallop beds along the Pacific coast is medium hard, with shells and eelgrass under mud or sand substrate. In Bahía Concepción, the catarina beds are harder, with shells, pieces of coral and gravel mixed with sand or mud. The beds in the Gulf of California are covered with brown and red algae. Santamaría-Gallegos et al. (1999) determined the coincidence in the timing of appearance of *Zostera marina* meadow and the reproductive time of scallops, and juvenile scallop settlement over the eelgrass meadow at Punta Arena, Bahía Concepción. The eelgrass meadow existing from December to May can provide scallops with a habitat to avoid predators (i.e., a refuge). In Ensenada de La Paz, beds are medium hard, with shells, sponges, soft corals and algae under mud.

The voladora scallop (*Euvola vogdesi*) beds in the Gulf of California around Isla Angel de La Guarda are usually sandy or alluvium substrate.

29.2.2 Fishing Seasons

The development of catarina and voladora scallop fishing because of the advent of the processing plant has meant scallops can be fished all year. Most scallops are exported as frozen muscle, mainly to the United States. The establishment of processing factories in 1974 revolutionised the scallop fishery and enabled the catarina scallop fishery to operate throughout the year, even in the warmest months.

Aguilar-Ruiz (1975) reported that in the Bahía de Los Angeles for *E. vogdesi* the 1972–1973 season lasted from January to January, with more than half the catch taken in the summer months. Félix-Pico (1991b) reported in Ensenada de La Paz the bay scallop season is from May to September with a peak (in 1975) from July to August. According to Baqueiro et al. (1981), the 1977–1978 season was from January to April and September to November with two peaks in 1977 in March and in October.

According to the statistical fishery data from the Secretaría de Pesca (Polanco-Jaime et al. 1987), the catch can be all year; however, there are defined dates of beginning and end of season for each fishing ground. In Lagunas Ojo de Liebre and Guerrero Negro, the bay scallop season is from May to December. In Laguna de San Ignacio, this season was from June to December 1981. In Bahía Magdalena, the season was, during 1980 to 1984,

from June to December. In 1983–1986, in Bahía Concepción, the maximum monthly catch was May to December.

The Ministry of Fisheries (SEMARNAP) is the legal authority. Survey and stock management is done by CRIP (Regional Fishery Centre). After 1990, the fishing season was set to be between May to June for *A. ventricosus* (Diario Oficial de La Federación 1990, 1993).

N. subnodosus had a fishing season during May to July and November and December of 1999.

29.2.3 Fishing Operations and Results

Unified effort data for scallops are scarce in México. The ideal measurement of effort would involve some measure of diving gear or number of divers per compressor and the time of diving, e.g., catch /No. divers h^{-1} . The catch is then reported as whole shellfish, meat, and muscle in kilograms. But usually effort data consist at best of catch per boat per day.

Aguilar-Ruiz (1975) reported that in Bahía de Los Angeles the recorded landings of *Pecten vogdesi* scallop from January 1972 to January 1973 varied from 5.3 kg muscle/boat day (1 kg muscle = 6.9 kg whole shellfish or 110 individuals) to 120 kg muscle/boat day $^{-1}$. The highest recorded catch in one month was 1,640 kg muscle in 18 fishing days - an average of 91 kg/boat day $^{-1}$. The average catch/boat day for the boats fishing during this period was 29–69 kg muscle/boat day $^{-1}$. The number of boats working Bahía de Los Angeles beds varied from 7 in January to 13 in June.

For the *Argopecten ventricosus* fishery, Félix-Pico (1991b) reported that at the Ensenada de La Paz grounds, catch averaged 29–35 kg muscle/boat day $^{-1}$ during the 1975 season. Baqueiro et al. (1981) on the same grounds reported the average catch was 25 kg muscle/boat day $^{-1}$ during the 1977–78 season. The number of boats working was 35 for 20 days. The highest recorded catch in one month was 5,000 kg muscle in 20 fishing days with all boats (1 kg muscle = 13 kg whole shellfish or 330 individuals).

The catch statistics for catarina and voladora scallop have been included amongst those for other shellfish, but in reality is almost entirely catarina scallop (Mexican Fisheries Statistics). The landings of scallop from 1981–1986 averaged 3,240 t year $^{-1}$. The highest recorded catch per year was 5,750 t. Scallops represented between 16% and 78% of total shellfish caught along the Pacific coast of México. In the Gulf of México, the recorded landings of shellfish from 1981–1984 was 1,500–2000 t year $^{-1}$, but there are no separate data on scallops. The data is in total fresh weight (Polanco-Jaime et al. 1987).

29.2.4 The Market Value-landings Data from 1970 to 2000

Landings of scallops in Baja California and Baja California Sur first became available in 1970; before this they had been included with other shellfish. As the voladora scallop landings increased in the late 1960's and early 1970's, the catarina scallop landings decreased from the 1975 peak to only 2.5 t in 1979, but they rose again as voladora

scallop decreased and have since been about 224 t. The voladora scallop landings achieved their greatest weight (4,380 t) and value (\$4,820,000 US dollars) in 1987.

The catch in México from 1970 to 2000 is given in Table 29.1. Catarina scallop catch is divided between those taken north of Baja California (Northwest Gulf of California) and those taken south of Baja California (Pacific coast and Gulf of California). Landings off northern Baja California were low in the late 1970's and early 1980's, and landings up to 1983 averaged 120 t year⁻¹. The highest recorded catch was 1,140 t (value \$6,400,000 US dollars) in 1987. The scallop catch off southern Baja California was low in 1979 with 2.5 t, but reached 900 t (value \$1 million US dollars) in 1981. It has been estimated that annual landings had risen to some 885 t by 1981–1987 and in 1986 they were 1,785 t (value \$4,460,000 US dollars). The number of boats in the scallop fishery had reached 95 in 1986. The data were taken from the statistical tables in the official bureau of SEMARNAP in La Paz and Ensenada. The values represent muscle weight in kilograms.

Major landings of catarina scallop occurred in 1989 and 1990, when 32,000 t and 28,000 t (whole weight) valued at \$12 million US dollars were landed. At present they are harvesting only 130 t (Fig. 29.4).

The fishery for *Nodipecten subnodosus* has harvested more than 1,400 t valued at \$2 million US dollars.

29.3 CONSTRAINTS

29.3.1 Pollution

In the Baja California Península, there is domestic and cannery sewage flowing into the bays, but there are no industrial wastes. There are small agriculture areas using pesticides.

Diseases of the scallop related to pollutants occurred in Ensenada de La Paz from 1977 until 1981. The rich organic soups created in inshore areas by domestic sewage outflows and sludge dumped into the bay contributed to increases in populations of facultative bacteria such as *Vibrio*, *Pseudomonas* and *Aeromonas*. Concentrations of such bacteria may provide sufficient infection pressure on scallops so that disease and mortality results. Evidence for this sequence of events can be found in studies done in polluted waters. Oseguera-Green (1977) reported scallops, water and sediments polluted by fecal coliform bacteria. At the present time, La Paz has a sewage processing plant and the pollution of Bahía de La Paz is controlled.

The implications of aquaculture development for human health assume importance in some coastal lagoons of Baja California Sur, but may gain further significance in the future. In some coastal regions, there is existing monitoring for regulatory control called the Mexican monitoring protocol for sanitation of mollusc bivalves (P.M.S.M.B.). This protocol began in 1973, and has been used in monitoring Laguna San Ignacio, Estero El Coyote (Pta. Abreojos), Bahía San Hipólito, Bahía Tortugas, Bahía Asunción and Estero Santo Domingo in Bahía Magdalena. Those sites have been shown to be of good quality for use of sea water in aquaculture (Treviño-Gracia 1995).

Table 29.1

Historical catch statistics for scallop species (*Argopecten ventricosus*, *Euvola vogdesi* and *Nodipecten subnodosus*), for the period 1970–2000. (Data from SEMARNAP, office in La Paz).

Year	Magdalena	Guerrero N.	La Paz	Concepción	Total Weight	Price	Value
	(t)	(t)	(t)	(t)	(t)	(\$US/kg)	(\$US/1000)

29.3.2 Biological Constraints

Natural biotoxins also pose public health problems, in particular, paralytic shellfish poisoning. The toxic dinoflagellates from the Pacific coast of México are *Gonyaulax polyedra*, *G. polygramma*, *Gymnodinium catenatum* and *Pyrodinium bahamense*. Some species in tropical and subtropical waters have long been known to be toxic. In the southern Gulf of California (Mazatlán, Sinaloa), dinoflagellate blooms or red tides have been reported during spring and summer causing toxic effects in fish and bivalves (Morquecho-Escamilla 1996). In the summer of 1986 in Bahía Concepción, blooms of dinoflagellates were noted but did not have any toxic effects on scallops and other bivalves. Morquecho-Escamilla (1996) established that during the highest peaks of dinoflagellate abundance, the potentially toxic species were *Dinophysis caudata*, *Ceratium furca*, *Prorocentrum micans* and *P. compressum*. By extracting the paralytic toxins (using mouse bioassays), Morquecho-Escamilla (1996) found the toxic activity in whole catarina scallop exceeded 400 MU, the maximum level allowed for human consumption of shellfish. Other toxic species; *Alexandrium catenella*, *Gonyaulax molinata*, *Gymnodinium catenatum* and *P. mexicanum* were identified in Bahía Concepción, Bahía de La Paz, and Laguna San Ignacio, B.C.S. (Garate-Lizarraga 1997). Possible pollution-mediated biotoxins should be an important consideration in planning aquaculture operations in these tropical waters.

29.3.3 Predation

The principal cause of mortality of *Argopecten ventricosus* is man, but natural mortality is caused by gastropods *Hexaplex nigritus*, *H. princeps* and *Phyllonotus erythrostomus*, fish (*Sphoeroides annulatus*, *Hoplopagrus guntheri*), stingray (*Heterodontus francisci*) and the crustaceans *Callinectes bellicosus* and *Cronius ruber* (Tripp-Quezada 1985; Félix-Pico 1991a).

Maeda-Martínez et al. (1992) determined survival using the potential predator impact (PPI) in four zones of Rancho Bueno and Bahía Almejas, which had previously been sown with tagged spat of catarina scallops (sizes 3 to 4 cm). Results show an inverse correlation with scallop size up to 4 cm. Scallops larger than these were not affected. The average PPI in Rancho Bueno was 80% in 48 h and in Bahía Almejas was only 25%.

A similar experiment has been made in Ensenada de La Paz, Lango-Reynoso (1994) released three thousand tagged scallops (average size 43 mm). The results show the number of scallops decreased from 106 to 5 organisms m⁻² in 56 days because of predator influence (96% mortality), with a predation rate of -0.19 x organisms eaten day⁻¹.

The catarina scallop community is composed of a large number of marine invertebrates that live on and within the shell. Although members of this community may indirectly affect the fishery, few of the species can be considered potential predators of the scallop. Pea crabs interfere with the normal feeding of scallops by ingesting strings of food filtered by the scallop, and cause chronic stress and reduce growth. In Bahía Magdalena, pea crab *Tumidotheres margarita*, (Crustacea: Pinnoteridae) infestation was found as high as 31% in adult *A. ventricosus*, between 47 and 56 mm shell height, and coincided with the spawning season of the scallop (Félix-Pico 1992).

In Bahía Magdalena, more than seventy-five species of invertebrates associated with scallops have been recorded, representing almost every major taxonomic group but crustaceans, polychaetes and molluscs are dominant. Heavy fouling covered 100% of upper valve surfaces and 30% of lower valve surfaces, adding considerably to the volume and weight of the catarina scallops. Three filter-feeders encrusting invertebrate species were dominant, *Megabalanus tintinnabulum*, *Tetraclina squamosa* and *Hydroides recurvispina*. The polychaetes *Nereis pelagica* and *Polydora rickettsi*, which inhabit space between the mantle and shell, cause the scallop to deposit extra shell layers. Consequent demands upon the scallop's energy may reduce growth or reproduction and may leave the weakened scallop prey to disease or to predators (Félix-Pico and García-Domínguez 1993).

In Laguna Ojo de Liebre and Estero El Coyote, Gómez del Prado (1984) reported more than 20 associated species of invertebrates, represented by the crustaceans *Fabia subcuadrata* and *Pinnotheres concharum* and molluscs. Other invertebrates of special interest because of their relation to the catarina scallop include *Echinocephalusseudouncinatus* (Nematoda: Gnathostomidae), which infects one host species, the horn shark, *Heterodontus francisci* (Pisces: Elasmobranchia). This final host eats scallops and becomes infected by ingesting the larval phase or cysts. The larvae occur in a high percentage of scallops seasonally, between 20% and 80%. The larvae also infect *Nodipecten subnodosus* as an intermediate host (Gómez del Prado 1983).

In Bahía Concepción, Gómez del Prado et al. (1992) reported *Phyllobotrium* sp. (Cestode) and a metacercariae (Family Fellodistomidae) infested 65% of catarina scallops. There is even less resemblance between species composition of the shallow areas of Bahía de La Paz and Bahía Magdalena, as described by Garduño-Méndez (1999). More than ten species were found in scallops in bottom culture, the copepod *Pseudomyticola spinosus*, a cestode larva (Family Phyllobothridae), and the turbellarian worms were prevalent. The coincident erosion of gill tissue and labial palps in some infested scallops suggests that *T. margarita* is a common parasite.

29.3.4 Resource Management Constraints

No legislative restrictions were placed on total catch of catarina and voladora scallops or on the efficiency or number of fishing units in scallop beds from 1970 to 1986. In the Baja California states, there are no limitations on daily total catch. Licenses are issued to those wishing to take catarina scallops commercially without any additional restriction of fishing grounds or number of fishing gears per ground. Management policies for the fisheries include licenses for both boats and personnel (3 boats and one diver per boat). The number of licenses for Bahía Magdalena and Bahía Concepción were 102 with 280 gears in recent years.

The capture of small scallops tends to be limited by the minimum size of shucked meat accepted by the processors. They accept 250–330 scallops kg^{-1} as a maximum. The maximum acceptable count per kg for *Argopecten ventricosus* is 330 scallops kg^{-1} , but the recommended is an average of 130 scallops kg^{-1} and the best size is 80 scallops kg^{-1} (Baquero et al. 1981; León-Carballo 1991; Félix-Pico et al. 1994), and for *E. vogdesi* is 173 scallops kg^{-1} with the minimum being 106 scallops kg^{-1} (Aguilar-Ruiz 1975). In addition, there are some minimum size limits imposed. In the Pacific coast beds, the recommended minimum size is 60 mm in the longest diameter, and along the Gulf of California coast is 56 mm (Diario Oficial de La Federación 1993).

The fishery for *Nodipecten subnodosus* is controlled, with a minimum size limit of 150 mm shell height, or 9 to 10 scallop muscles kg^{-1} and quotas limited to 1–2 t per license (25 kg muscle day^{-1}). The number of licenses per season was between 30 and 44 (Morales-Hernández and Cáceres-Martínez 1996).

29.4 HARVESTING AND TRANSPORTING

29.4.1 Methods

In the Baja California states, catarina and voladora scallops are usually consigned to a particular dealer, with scallops being sold by muscle weight or viscera weight. Many landings are made in remote places, and it is necessary to transport them by refrigerated trucks over considerable distances. Scallops landed in Lagunas Ojo de Liebre or Guerrero Negro might be taken to be sold in Ensenada or Tijuana, Baja California. Scallops landed in the Laguna San Ignacio, Bahía Concepción, and La Paz are sent to the continent,

especially Mazatlán, Guadalajara, Monterrey and México City. Most scallops are exported as frozen muscle to the United States and some are marketed as canned.

Meat extraction, known as shucking, is a manual operation for catarina, mano de león and voladora scallops. The shell is opened by inserting a sharp knife along the inside of the flat valve. The viscera are then removed from the round valve, leaving the adductor muscle and roe attached and easily cut away. The whole operation, usually performed by a team of women, is done with amazing speed. The catarina scallops are opened, the flesh is then detached by shaking or by pushing with the finger, and the adductor muscle is pushed out from the rest of the viscera.

The smaller size meat is scalded in boiling water for few minutes; this usually to be sold to the home market.

The muscle meat is shucked, washed, and packed in plastic bags (5 pounds) for freezing and then mostly exported to the United States. New packaging is now used. Seal-top is a hermetically sealed, resistant, and reclosure overcap with printed specifications.

The food processing technology centre in Hermosillo, Sonora, studies quality conditions of frozen scallop muscles and have made flavoured, smoked, marinated, lyophilised, and cold binding or blending scallops (Ocaño-Higuera 1999).

29.4.2 Marketing

The home market for scallops is small because of the high price, though it is growing. Most, however, are exported to the United States of America. In addition to scallops sold as frozen meat, most scallops are exported as frozen muscle. There is no market in Baja California Sur for live scallops in the shell. The scallops are sold by the hundredweight and are usually consigned to a particular dealer or processor. The price in 1987 was \$0.62 US dollars kg^{-1} and the price of scallop meat (muscle plus roe) varies according to the season from \$2.25 to \$3.41 US dollars kg^{-1} (Pérez-Concha 1990). The price of muscle only was \$5.00 US dollars kg^{-1} and whole weight was \$0.40 to \$1.82 US dollars kg^{-1} in recent years (1997–1999). All the prices were paid by the dealer to fishermen at the beach.

The fishery statistics in Figure 29.4 and Table 29.2 illustrate how the states of Baja California contribute to the national production. Approximately 80% of scallop production from México is processed (muscle), and 82% of this processing is imported by The United States of America. In 1987, 380,000 kg of frozen muscles were exported. In the first months of 1988, 245,000 pounds of frozen muscle were exported (from Fishery Market News Report, January 1987 to March 1988; U.S. Department of Commerce).

The best prices are usually obtained in August to January in the U.S.A. market and Table 29.2 shows recent market prices for frozen muscle, an almost doubling in price. The Mexican scallops are small and cheap. There were plenty of Florida calicos and Chinese bays at prices averaging between \$1.80 and \$2.50 US dollars lb^{-1} , depending on size, through the winter of 1995.

Table 29.2

Historic number of licenses (2 or 3 boats), landed weight of sucked meats, price per kg, total values and percentage of exported to USA for 1978–2000. (From SEMARNAP (1999), Pérez-Concha (1990) and Massó-Rojas (1996)).

Year	No. of Licenses	Landings Muscles (t)	Price (\$US/kg)	Total value (\$US)	Exported to USA (%)
1978	7	33	2.85	\$94,367	30
1979	12	1	3.25	\$1,806	40
1980	12	127	4.32	\$550,080	50
1981	11	313	4.12	\$1,290,933	55
1982	14	275	3.77	\$1,037,169	40
1983	23	232	3.89	\$901,183	55
1984	20	256	4.90	\$1,255,489	55
1985	13	270	4.52	\$1,219,396	64
1986	17	633	4.02	\$2,542,873	90
1987	10	626	3.61	\$2,258,256	90
1988	63	1,217	3.41	\$4,148,454	91
1989	135	3,558	3.25	\$11,564,944	92
1990	300	3,247	4.10	\$13,311,333	85
1991	230	769	3.85	\$2,958,939	82
1992	59	105	4.30	\$452,933	55
1993	32	144	4.88	\$704,889	60
1994	45	52	5.86	\$307,324	58
1995		102	6.30	\$645,400	70
1996		1,874	4.50	\$8,432,000	85
1997	102	173	5.40	\$935,400	90
1998		212	4.20	\$889,933	68
1999		14	5.25	\$75,833	45
2000		20	6.40	\$128,000	55

29.5 EXPECTED FUTURE

The Mexican scallop fishery has come a long way in three decades, from a dwindling overfished resource to a major fishery and culture in terms of tonnage and value. This success is caused by many factors integral to the Mexican society; the government fishery bodies, cooperatives, fishermen and scientists reacting quickly and sensibly to the problem of dwindling stocks and catch. There were also well established legal precedents for the exploitation of grounds, and for the development of culture in coastal areas where the long line installations were protected from industrial and other developments.

The growth of the scallop diving industry has been spectacular over the past few years, and its role in scallop conservation can be credited with creating employment through processing and handling of scallops. Practical culture depends on family labour of all ages. The balance of payments of México is helped through foreign earnings on exports. Methods of working scallops are now becoming standard, and the divers involved are putting a great deal of thought into running cost conscious and profitable operations. The new awareness of fishery bodies of the importance of environmental quality for the future of their scallop industry should result in a stable industry with healthy market outlets in the years to come.

29.6 AQUACULTURE

29.6.1 Introduction

At the present time, scallop aquaculture consists of culturing local species. Satisfactory results have been obtained by several culture facilities but there have not been any great advances in production. Aquaculture of pectinids, although rapidly developing, has production volumes <0.5% of the total landings (Table 29.3). Progress to massive production of pectinid species seed in hatcheries and their transference to the natural environment for growout has been successful. Future emphasis will be in selecting scallop species or producing hybrids that have improved qualities over local species. Strain evaluation and selection have been done, mass and family selection programs have been initiated, and intraspecies crossbreeding established (Cruz-Hernández and Ibarra 1997b; Ibarra 1999; Ruiz-Verdugo et al. 2000).

Table 29.3

Summary of the scallop aquaculture production, for the period 1988–1999. (Data from Maeda-Martínez et al. (1996), Mazón-Suástegui (1996) and SEMARNAP (1999)).

Year	Production (t) FAO (1999)	Production (t) SEMARNAP	Number of Spat Cultured	Origin
1988	20	15	340,000	Natural, hatchery
1989	20	30	60,000,000	Natural
1990	30	1,800	92,000,000	Natural
1991	10	576	478,000,000	Natural
1992	60	72	172,000,000	Natural
1993	60	47	2,000,000	Natural
1994	41	55	600,000	Natural, hatchery
1995	14	180	9,000,000	Natural, hatchery
1996	10	10	900,000	Natural
1997	10	10	200,000	Natural
1998	-	10	250,000	Natural
1999	-	200	9,000,000	Natural, hatchery
2000	-	200	10,000,000	Natural, hatchery

29.6.2 Species

The catarina scallop, *Argopecten ventricosus*, is the most studied and cultured scallop species in México. Other scallop species, *Nodipecten subnodosus* and *Euvola vogdesi*, are under study using some of the techniques developed and with the availability of hatchery-reared seed scallop.

29.6.3 History

Scallop culture research has just begun (Amador-Buenrostro 1978; Félix-Pico et al. 1980; Siewers 1982; Baqueiro 1984; Reyes-Sosa 1985; Tripp-Quezada 1985; Félix-Pico et al. 1989). The catarina scallop, *A. ventricosus* is cultivated because of its high value and fast growth. Many studies have been made on the techniques for the natural seed collection, broodstock conditioning, larvae rearing, and setting and growout of the spat at coastal sites. Investigations into hatchery cultivation of scallops have also been done and there has been successful work in management to obtain maximum production levels in suspended and bottom culture.

Under natural conditions, the catarina scallop spawns from late February to March when the water temperature rises from 19°C to 21°C (Félix-Pico et al. 1980). The pelagic larvae attach to spat collectors twenty days after spawning and are allowed to grow to about 8–12 mm. The juvenile scallops are put in plastic cages containing about 500 individuals at the start of culture, then reduced to a density of 50 individuals in the final culture. Market size (5–6 cm) is reached in about 6–8 months (Félix-Pico et al. 1989). The bottom culture practice in enclosed areas is adapted to shallow waters, where juvenile scallops are protected by plastic nets from benthic predators (Baqueiro 1984; Cáceres-Martínez et al. 1987; Singh-Cabanillas 1987).

Attempts have been made to rear only the bay scallop to market size, with spat produced in the laboratory reared to metamorphosis in laboratory pilot testing (Mazón-Suástegui 1986; Coronel-Solorzano et al. 1987; Avilés-Quevedo and Muciño-Díaz 1988a; Avilés-Quevedo and Muciño-Díaz 1988b). The first commercial hatchery production at the Centro de Investigaciones Biológicas del Noroeste (CIBNOR) was around 20,000 spat by Maeda-Martínez et al. (1989). The government hatchery at Bahía Magdalena (SEMARNAP) and this produced 325,000 spat (Mazón-Suástegui et al. 1991), and the state hatchery called Centro Reproductor de Especies Marinas del Estado de Sonora (CREMES) and this at Sonora began to sell seed at \$1 US dollar per 1,000 (Robles-Mungaray and Serrano-Guzmán 1993, 1995). Cage culture can produce scallops in eight to 14 months, making the scallop a prime candidate for aquaculture.

No previous research on aquaculture for the commercial scallop *Nodipecten subnodosus* is known, just two works on larval rearing and wild spat. Carvajal-Rascón (1987) reported spat production to describe the larval cycle in laboratory and this species has been reared to metamorphosis in pilot testing. Another is about spat settlement and early growth in Laguna Ojo de Liebre (García-Domínguez et al. 1992).

There is a similar situation for *Euvola vogdesi*, with observations on spat settlement in collectors and growout in Bahía de La Paz (Cáceres-Martínez et al. 1989; Ruiz-

Verdugo and Cáceres-Martínez 1991) and in Bahía Bacoichampo (Carvajal-Rascón and Farrell 1984). Attempts were made to produce juveniles from the laboratory pilot testing (Monsalvo-Spencer 1994), and a few thousand spat have been raised in the hatchery (personal communication, Miguel Robles).

29.7 HATCHERY TECHNIQUES

29.7.1 Conditioning

Laboratory experiments were done to determine the effect different temperatures and food levels might have on the timing of various stages of the reproductive cycle. Avilés-Quevedo and Muciño-Díaz (1988b) also reported diets to feed *Argopecten ventricosus* scallops to maturation. Gonads ripen when ambient water temperature is 17°C to 19°C, and with a food level increase from 4,000 to 5,000 million cells scallop⁻¹ day⁻¹ or at a concentration between 1 to 1.5 million cells mL⁻¹ of *I. galbana*. Completely mature specimens were produced in 4 weeks. A broodstock-conditioning method was described by Mazón-Suastegui et al. (1986), when they were fed with a mixture of cornstarch and microalgae and conditioned in flow-through flumes provided with raw seawater at 20°C. The method was enhanced by Avilés-Quevedo et al. (1991) by optimising the clearance rate to maximise food assimilation and avoid pseudofeces production.

Catarina scallop have been cultured successfully at a commercial level from spawning to harvest size. Results indicate that recently spawned broodstock can be matured to spawning in 4 weeks at 23 ± 1°C and with a food ration of 3,900 million cells scallop⁻¹ day⁻¹ of a mixture (6:3:1) of *I. galbana*, *Chaetoceros* sp. and *Tetraselmis suecica* (Maeda-Martínez et al. 1989, 1995; Maeda-Martínez and Ormart-Castro 1995; Lora-Vilchis et al. 1997).

Scallops can be conditioned out of season in the laboratory by holding them in a cold room (20 ± 1°C) for 5 weeks with daily additions of *I. galbana* and *C. gracilis* (50:50), with the ration at 9% of the initial dry weight of the gonad or 50,000 cells mL⁻¹ day⁻¹ (Millán-Tovar 1997).

Racotta et al. (1998) investigated whether continuous rather than discontinuous feeding could improve reproductive performance of *A. ventricosus* during conditioning in the hatchery. The gonadal biochemical composition was analysed. Protein was 35% to 45% of dry weight or 75 mg g⁻¹, acylglycerols were 4 to 18 mg g⁻¹, and cholesterol (3.8 to 4.9 mg g⁻¹) and glucose (5 to 5.6 mg g⁻¹) were slightly higher. They concluded a continuous feeding system resulted in a better spawning capacity and increased rematuration ability than discontinuous feeding.

The continuous feeding system was optimised by using an agricultural drip system and a permanent supply of food in multiple rearing tanks. That result contrasted with the discontinuous system for conditioning scallop broodstock, for which the large amounts of food required, added in intervals, resulted in pseudofeces being produced and in a large variation in food availability and therefore of the microalgae removal rate (Ramírez and Ibarra 1999).

Carvajal-Rascón (1987) reported a broodstock of *Nodipecten subnodosus* conditioned for 8 weeks at 19°C, and fed a mixture of *Pavlova lutheri* and *Pseudoisochrysis* sp. algae, keeping concentrations at 1 to 2 million cells mL⁻¹. Gutierrez-Villaseñor and Chi-Barragán (1997) kept a population of the same species 6 weeks at 17°C to 18°C and then gradually raised temperature 2°C every four weeks, with a microalgal diet of *Monochrysis lutheri* and *Isochrysis galbana*. The scallops were also given the microalgae T-Iso daily so that it represented 3% or 1.7% of the dry weight of each organism. In a commercial hatchery (CIBNOR) at La Paz, a broodstock of *A. ventricosus* had been conditioned by maintaining the animals at 24 ± 1.5°C, and fed daily on a diet of *I. galbana*, *M. lutheri*, *Thalassiosira pseudonana*, and *C. gracilis* for 5 weeks at a concentration at 150,000 cells mL⁻¹ in the proportion of 3:3:2:2 (Villavicencio-Peralta 1997).

29.7.2 Induction of Spawning and Fertilisation

Gametes are usually obtained by inducing ripe adult scallops (*A. ventricosus*) to spawn. Ripe scallops are placed in a tank or trough. The scallops are held at 30 °C for about 1 h and then the temperature decreased to 25°C until the scallops appear to be pumping vigorously, first male spawning and then after 20 min the females (Avilés-Quevedo and Muciño-Díaz 1990). Additionally, other authors induced spawning using the high algal density method (Mazón-Suástegui et al. 1991).

The spawning process has been induced by thermal shock and chemical (serotonin) stimulation for a broodstock of *A. ventricosus* (Ibarra et al. 1995; Lora-Vilchis et al. 1997; Monsalvo-Spencer et al. 1997). A broodstock of mature scallops collected from Bahía Magdalena was induced to spawn by each of the scallops being injected with 0.2 mL of serotonin (5-hydroxytryptamine, 0.5 nM) in the gonad (Ibarra et al. 1995). Adult specimens of *A. ventricosus* were collected from Bahía de La Paz, B.C.S. and were conditioned to gonadic maturity in the laboratory for 25 to 30 days. Two spawning procedures were used. Thermal shock consisted of a sudden increase from 24°C to 26°C, held for 45 min and then raised to 27°C and held 15 to 20 min until the sperm was observed. For the serotonin procedure, 0.4 mL of a 0.125 mM solution of serotonin diluted in filtered seawater was used (Lora-Vilchis et al. 1997).

For *A. ventricosus*, Monsalvo-Spencer et al. (1997) induced spawning with thermal shock (increasing 3°C/min from 18°C to 30°C) combined with addition of sexual products from another individual. This was effective as a spawning inducer in 50% of the breeders and was the only treatment that induced oocyte release after 3 to 5 h. Spawning was also induced with injection of serotonin (5-hydroxytryptamine at 0.025, 0.25 and 2.5 nM) and was effective as a sperm releaser only. Fertilisation was made with a proportion of 7 sperm per oocyte and 90% fertilisation obtained. Oocyte size averaged 53 µm.

Broodstock of *A. ventricosus* and *N. subnodosus* were conditioned at the CREMES at Bahía Kino, Sonora, and were successfully induced to spawn with thermal shock (ΔT from 18°C to 29°C). "D" larvae of *A. ventricosus* and *N. subnodosus* were found between 20 to 24 h after fertilisation with a length of 70 to 90 µm and height of 60 to 75 µm for the former, and a length from 80 to 100 µm and height from 65 to 70 µm for the latter (Serrano-Guzmán et al. 1997).

Spawning was obtained with thermal shock for *N. subnodosus* (Gutierrez-Villaseñor and Chee-Barragán 1997). More than half of the organisms spawned only as males, followed by those that spawned as both, and only a few spawned only as females. A similar behaviour has been found in other pectinids. Other authors used thermal shock (ΔT from 18 to 28°C) with successful induction (Velasco-Blanco 1997; Villavicencio-Peralta 1997).

29.7.3 Larval Culture and Metamorphosis

The catarina scallop has been reared to metamorphosis in pilot testing. The veliger larvae were cultured at 24°C and 35‰ salinity. After 10 days the velum (size 194 x 228 μm) was absorbed and a big foot developed. Between 14 to 16 days of fast growth, there was a shell without ribs (Avilés-Quevedo and Muciño-Díaz 1988a). When 60% of the larvae reached the eyed pediveliger stage, two basic arrangements for setting larvae were immersing a plastic mesh as substrate into the tank (bag collector), and depositing larvae in a continuous flow fibreglass-sieve containers, filled with or without plastic mesh collectors. Filtered seawater and microalgae were supplied twice a day for the culture tanks and continuously in the sieve containers (Mazón-Suástegui et al. 1991).

Monsalvo-Spencer (1998) placed free-swimming veliger "D" larvae after hatch-out (24 h) in a 100-L larval rearing tank with rearing densities of 10 larvae mL^{-1} . Daily feeding consisted of keeping a concentration of 60,000 cells mL^{-1} of a mixture of *I. galbana*, *Chaetoceros* sp. and *T. suecica* (6:3:1) over 6 days. After the shell height was 85 μm , density was reduced to 6 larvae mL^{-1} and they were fed with 100,000 cells mL^{-1} . Finally, density was reduced to 3 larvae mL^{-1} and fed with 150,000 cells mL^{-1} . The larval settlement (176–188 μm) occurred after 15 days and the temperature raised from 23 to 24°C. This period can be adjusted with the linear equation:

$$\text{Shell height} = 54.12 + 6.1 * \text{days} \quad (8)$$

Metamorphosis and setting were allowed to proceed on a nylon screen (30-cm diameter and 140- μm mesh), immersed in a 70-L container with running seawater at 0.5 L min^{-1} . The screens were changed to 160, 180, 212 and 250 μm as the larval size increased (Fig. 29.5). Juveniles were maintained until reaching 2 mm at 45 days. This period can be adjusted with the exponential equation:

$$\text{Shell height} = e^{(5.04 + 0.055 * \text{days})} \quad (9)$$

A successful culture and high yield is assured by changing water every three days until larval development is complete and the larvae are ready for settlement (Monsalvo-Spencer (1998). The larval rearing tanks are maintained with no water flow and soft aeration to avoid injuring the larvae. The larval rearing apparatus represents an advancement in scallop cultivation procedures, and the authors have obtained a patent (No. 180212) for this container (Maeda-Martínez et al. 1995; Maeda-Martínez 1996).

Figure 29.5. Laboratory growth of *Argopecten ventricosus* from fertilised egg to 15 day post fertilisation. Calculated by equations number 8 and 12. (From Serrano-Guzmán et al. (1997) and Monsalvo-Spencer (1998)).

Ibarra et al. (1995) studied the effects of inbreeding on growth and survival of self-fertilised catarina scallop larvae. This study was done at the Genetic Laboratory in La Paz (CIBNOR). The larvae were placed in 20-L experimental tanks. Daily feeding consisted of adding *I. galbana* at varying concentrations depending on age; 75,000 cells mL⁻¹, 100,000 cells mL⁻¹, and 150,000 cells mL⁻¹ for larvae up to 3 days old, up to 6 days old, and up to 18 days old. The larvae produced from exclusive self-fertilisation and grown over a period of 18 days are smaller (112 µm) and have lower survival (31%) than larvae produced from either pair-mating (121 µm; 54%) or mass-spawning (118 µm; 56%), which latter two were not significantly different. At the end of rearing period, larvae with an inbreeding coefficient of $F = 0.5$ showed a decreased length of 12% and 11% and a reduced survival of 43% and 41% compared to mass-spawned and pair-mated groups.

Another factor that has an effect on growth and survival is the stocking density. Ibarra et al. (1997), with two populations of catarina scallop, tested larvae from Bahía Magdalena at densities of 10 to 20 larvae mL⁻¹, concluding the lower density had higher growth but equal survival. Larvae from a Bahía Concepción population grew better at densities of 15 and 20 larvae mL⁻¹ than densities of 5 and 10 larvae mL⁻¹, although survival was lower at higher densities. The average seawater temperature was 21 to 22°C.

In both experiments, feeding was by adding, once a day, a mixture of *I. galbana* and *M. lutheri* (1:1) in concentrations of 30 cells μL^{-1} for 2–5 days, 50 cells μL^{-1} for 6–7 days, 60 cells μL^{-1} for 8–9 days, and 80 cells μL^{-1} for 10–14 days.

Several studies had been done on algal diets that yield fast growth and high survival in scallop larvae. Lora-Vilchis and Maeda-Martínez (1997) determined the nutritional values of ten microalgae species by studying the ingestion and digestion index of *A. ventricosus* veliger larvae during 7 days. Results showed a significant positive correlation between the smaller geometric dimension of the algae and the larval age and size of initial ingestion. Only *I. galbana*, *M. lutheri*, *C. calcitrans*, *C. muelleri* and *Thalassiosira pseudonana* clone 3H were ingested, and *Nannochloris oculata* and *Phaeodactylum tricornutum* were ingested but not digested. No ingestion was observed in *Tretaselmis suecica*, *Dunaliella tertiolecta* and *Thalassiosira pseudonana* clone s78 during the experiment.

Millán-Tovar (1997) found larvae of *A. ventricosus* could be cultured with a diet of *I. galbana* and *C. gracilis* (1:1) with the best growth rate of 11 $\mu\text{m day}^{-1}$ and larval settlement after 16 days with the highest percentage.

The state hatchery CREMES at Sonora has cultured catarina and mano de león scallops in 3.5-m³ tanks, in one trial in 1992 and two in 1993. Both culture systems followed the methods described by Robles-Mungaray and Serrano-Guzmán (1993, 1995) until larval settlement. “D” larvae of *A. ventricosus* and *N. subnodosus* between 20 to 24 h after fertilisation had a length from 70 to 90 μm and height from 60 to 75 μm for *A. ventricosus*. *N. subnodosus* larvae were 80 to 100 μm long and from 65 to 70 μm high. The prodissococonch II of catarina scallop (90 to 95 μm long) were observed after the second day and *N. subnodosus* prodissococonch II were present after the third day. The umbo stage for *A. ventricosus* (120 to 160 μm long and 105 to 150 μm height) appeared at the third day and that of *N. subnodosus* (150 to 185 μm long and 120 to 150 μm height) on the eighth day. Pediveliger with eyespot of catarina scallop (240 to 250 μm long and 215 to 220 μm height) were seen on day eight and for *N. subnodosus* (190 to 210 μm long and 165 to 180 μm height) on day eleven. *A. ventricosus* dissoconch starts between the eighth and the ninth days (>250 to 255 μm long and >220 to 230 μm high), and *N. subnodosus* dissoconch begin between the 12th and the 13th days (>210 to 215 μm long and 180 to 190 μm height).

Isometric larval growth occurred in both species following a linear model described by the equations:

$$L = -3.1 + 0.9 * \text{height with } R = 0.99 \text{ for } A. \text{ ventricosus}, \quad (10)$$

$$L = -11.5 + 0.9 * \text{height with } R = 0.99 \text{ for } N. \text{ subnodosus}. \quad (11)$$

A. ventricosus grew exponentially with time, leads however to giving the equation:

$$L = 60.5 e^{0.18 - \text{days}} \text{ with } R = 0.99, \quad (12)$$

Whereas *N. subnodosus* grew linearly with time described by the equation (Fig. 29.6):

$$L = 71.8 + 10.8 \text{ l * days with } R = 0.99. \quad (13)$$

The highest growth rate in *A. ventricosus* was between the third and the seventh days (Serrano-Guzmán et al. 1997).

Carvajal-Rascón (1987) has reared *N. subnodosus* to metamorphosis in pilot testing, and described the morphological changes. Veliger larvae were observed between 21 to 24 h after fertilisation, with a density between 30 to 150 eggs mL⁻¹, and were fed algae at a concentration of 30,000 to 300,000 cells mL⁻¹ under ambient temperature that averaged 26°C. After 10 days of culture, they reached a length 197 µm, with a growth rate of 6 µm day⁻¹. Larvae were dead before metamorphosis.

The CIBNOR, Centro de Investigación Científica y de Educación Superior de Ensenada, B.C. (CICESE), and Universidad Autónoma of Baja California (UABC) laboratories have cultured *N. subnodosus* (Ortiz-Cuel 1994; Velasco-Blanco 1997; Villavicencio-Peralta 1997). The larvae were reared at densities of 2 to 7 larvae mL⁻¹ under ambient temperature that averaged 19.5°C for the first week and 24.5°C for the second week. In one experiment, four different rations of the microalgae *Isochrysis* var. *galbana* aff. *thaitiana* were used (1,250, 2,500, 3,750 and 5,000 cells larvae⁻¹ day⁻¹ in the first week, and the second week at 2,500, 5,000, 7,500 and 10,000 cells larvae⁻¹ day⁻¹). During the second experiment, four larval densities were used (2, 5, 7 and 10 larvae mL⁻¹) with a constant ration of 3,000 cells larva⁻¹ day⁻¹. The average larval growth rate at the higher rations averaged 6.1 µm day⁻¹ during the two week period. Larval survival was reduced from 63% to 34% and from 84% to 45% by the increased culture density the first and second week of the experiment. Temperature had an appreciable effect on the larvae. Results showed that low to medium rations, low densities, and temperatures above 20°C are the most favourable for the larval culture of this species (Ortiz-Cuel 1994; Ortiz-Cuel et al. 1997).

Similar results were obtained by Velasco-Blanco (1997). Using a mixture of microalgae *I. galbana* and *C. calcitrans*, growth and survival rates were an optimum. Chemical analysis showed that microalgae *I. galbana* are higher in protein, lipid and carbohydrate and *C. calcitrans* was a complementary food. Villavicencio Peralta (1997) made a mixture with both algal species and *Nannochloropsis oculata*. These species produced an average larval growth rate between 0.7 and 1.6 µm day⁻¹. The temperature was about 27°C. The veliger "D" larvae occurred 18 h after fertilisation and larval settlement was at 16 days.

Figure 29.6. Larval growth of *Nodipecten subnodosus* from fertilised egg to 15-day post fertilisation. Calculated by equation number 13. (From Robles-Mungaray and Serrano-Guzmán (1993)).

Larvae of *N. subnodosus* were reared to evaluate the performance of downwelling screen as a settlement system in the laboratory (acrylic laminate of 112 x 27.5 x 29 cm). Each chamber received 30,000 mature larvae with a mean length of 190 µm. At the beginning of the experiment, the food provided was 30,000 cells mL⁻¹ of a 1:1 mixture of *Isochrysis var. galbana aff. thaitiana* and *T. pseudonana*, which was gradually increased to 50,000 cells mL⁻¹ after 4 weeks. The settlement of the larvae occurred during a protracted period of 15 days after which no swimming larvae were observed. Survival to the fourth week, as reflected in spat numbers, was significantly higher in the chambers without additional substrate (González-Ramos et al. 1997).

Larvae of voladora scallop (*Euvola vogdesi*) had been cultured in 4000-L rearing containers in the CIBNOR hatchery. The rearing and settlement methods used are similar to the process adopted for *A. ventricosus*, and preceded routinely along lines established by other workers (Maeda-Martínez et al. 1989; Avilés-Quevedo and Muciño-Díaz 1990; Robles-Mungaray and Serrano-Guzmán 1993, 1995; Monsalvo-Spencer 1994). Under optimum conditions, a high percentage of larvae metamorphosed with low mortality to 11 to 13 days after fertilisation. Successful sets were produced with 3 larvae mL⁻¹. The best results in management of these spat were obtained by rearing them to 3 to 4 mm in the hatchery. The first attempt was with 60,000 juveniles, and the second near one million juveniles (Miguel Robles, personal communication).

29.7.4 Genetic Enhancement

29.7.4.1 Selection

The practice of selection relies on using the most desirable individuals within a population to produce the subsequent generation. The principle of selection is based on heritability of the trait and its relation to the intensity of selection. In bivalves, these are represented as shell traits; total length, height and width, and as whole weight. These growth variables can be measured without sacrificing the individuals. Ibarra et al. (1999) did an experiment by using one-generation selection for total weight and shell width at age 1 year in catarina scallop *A. ventricosus*. These selected lines were used to estimate direct and correlated responses to selection, produced heritabilities, and produced genetics. An experimental base generation was produced under laboratory conditions from a population at Laguna Rancho Bueno, in Bahía Magdalena. Growout was in the same lagoon. Larvae and spat were reared in the CIBNOR Genetics Laboratory at La Paz, B.C.S. Results were that two traits have high genetic correlation, evidenced by the high correlated response of shell width when selecting on total weight.

Similar results were obtained by Ibarra (1999) with the total weight. Correlated responses of all growth traits were large at the age of the selection (1 year), and at 5 months. For the most important trait in scallop, adductor muscle weight, and correlated gains of 13% to 19% are expected when selecting the heaviest 10% individuals. The same correlated response is expected for tissue weight. However, that was not true for shell width. No significant positive correlated responses at 5 months were seen for any trait, but negative correlated responses for shell height and shell length were significant at 1 year. Further studies need to be done to establish whether negative correlation of these traits, and for scallops, whether this results in a negative effect on muscle weight and on reproductive performance. The importance of stock selection is emphasised not only for juvenile or adult phenotypic traits of artificially-produced progeny, but also on the maternal quality of the spawners producing that progeny (Cruz-Hernández and Ibarra 1997a).

29.7.4.2 Crossbreeding

The evaluation of crosses among the populations is also important, because it might indicate whether the best breeding method would be crossbreeding. Crossbreeding would be the preferred method when heterosis for production traits occurs. There are two important catarina scallop fisheries along the Baja California Península, Bahía Magdalena and Bahía Concepción. Intra- and intercrosses between scallop populations from those two fisheries were produced and simultaneously grown under those two different environments. Cruz-Hernández and Ibarra (1997b) determined environmental effects on growth, and whether a genotype by environmental interaction is present that will cause the best genotype to be different for each environment.

During the larval stages, there was a clear maternal effect for survival and length, evidenced by a difference between the reciprocal crosses and a similarity of each

reciprocal cross to its maternal parent. The presence of maternal effects was explained as egg energy reserves being different between the two populations, possibly caused by different environmental conditions during the initial gametogenesis process of spawners. Larvae from Magdalena population and the reciprocal cross produced with those eggs had a higher survival (46% and 47%) than larvae from the Concepción population and its maternal reciprocal cross (32% and 29%). The best larval growth rate was from Magdalena, reaching 167 μm , higher than Concepción at 140 μm . Similar results for the reciprocal crosses (160 and 153 μm) were obtained. The presence of maternal effects is explained because egg energy reserves are different between the two populations despite the simultaneous conditioning of 15 days for both groups of spawners prior to spawning induction (Cruz-Hernández and Ibarra 1997a).

During the simultaneous growout at Bahía Magdalena and Bahía Concepción to age 4 months, the environmental effect was the main determinant for growth and survival of the genetic groups. At Bahía Magdalena, there was a better performance of all genetic groups than at Bahía Concepción, which is explained as a consequence of a larger environmental stress in the latter site (low productivity and higher average annual temperature). These results suggest that Bahía Magdalena is a growout area with better environmental conditions for the growth of catarina scallops. The populations were differentiated during the last month in both environments, but only by shell width when grown in Bahía Magdalena, whereas when grown in Bahía Concepción genetic differences between the populations were seen for all growth traits and survival. For shell width, the best population in each environment was the one native to that bay, which resulted in significant of the interaction between genotypes and environments for this trait (Cruz-Hernández et al. 1998).

For survival, the genotype by environment interaction resulted not only from the poor performance of the Magdalena population when grown at Bahía Concepción, but also from a poor performance of the reciprocal crosses. At the end of the culture, the largest heterosis for growth was seen in Bahía Concepción (>15%) for the biomass trait. There was no heterosis for survival in either of the environments evaluated. For both hatchery and growout stages, and despite some growth heterosis, this cannot be considered a useful heterosis at the production level, because the reciprocal crosses were similar to the population with the best growth, never exceeding either of them significantly (Cruz-Hernández et al. 1998).

29.7.4.3 Triploidy

Production of triploid bivalves has been successfully achieved with many commercially important species of scallops. This practice had been used for the catarina scallop *Argopecten ventricosus* using two concentrations (0.1 and 0.5 mg L^{-1}) of cytochalasin-B (CB), applied for 15 min to inhibit extrusion of the second polar body (PBII). Results showed that the triploid percentage average ranged from 8.3% to 57.5%. Triploid individuals were obtained in both CB concentrations, but the triploid induction was low (8.3%) when using 0.1 mg L^{-1} . No triploid spat were detected in the controls. The highest level of triploidy (57.5%) was obtained with 0.5 mg L^{-1} . Cytochalasin B

treatment of scallop eggs resulted in a lower survival than controls for both larval and spat stages (2% to 16%). One difficulty with triploid induction in this species is associated with the characteristic of hermaphroditism (Ruiz-Verdugo et al. 1997).

Growth of triploid scallops exceeds that of diploids in all evaluated traits. The largest percent difference between the diploid control group and the treated groups were seen after diploid scallops reached the peak of sexual maturation and began spawning. The gonad of the triploid had a brownish discolouration, few oöcytes and sperms developed, and male acini were replaced by female acini. Gametogenesis and the condition of hermaphroditism in this normally functional hermaphrodite were greatly affected by the triploid condition. At 280 days, the muscle index was larger than the control group, with an inverse relationship between the muscle index and gonad index in the control group, which when compared with diploid scallops from within the same treatment, had a significantly larger muscle weight than the differences seen between the treated and control group (Ruiz-Verdugo et al. 2000).

29.7.5 Antibiotics

Sick larvae in a culture exhibit slow growth, poor colour, slow ciliary movement, loss of velum, accumulation of lipid granules in the digestive system, empty stomachs and weak swimming activity (finally sinking to the bottom and dying). Sick larvae usually stop feeding, so a low rate of algal consumption will also indicate a problem. Sainz-Hernández et al. (1998) experimentally induced vibriosis with *Vibrio alginolyticus* in larvae of *Argopecten ventricosus* in a laboratory hatchery and determined that these bacterial infections came from seawater and freshwater effluents, and the broodstock. Under concentrations of 0.5×10^5 cells mL⁻¹ or lower, *V. alginolyticus* was innocuous (80% survival), but at 5×10^5 cells mL⁻¹, there was no larval activity by day 10, nor had any larvae survived by day 12.

Adding chloramphenicol and erythromycin, effective antibiotics against both Gram-negative and Gram-positive bacteria, to the larval rearing water helps suppress bacterial growth. Both antibiotics helped increase survival in *Argopecten ventricosus*. The results obtained with the food algae (*Isochrysis galbana* and *Chaetoceros gracilis*) showed growth rates were not affected (Campa-Córdova 1997).

Chloramphenicol and erythromycin are added to the seawater in the rearing container to obtain the desired concentrations, 0.5 to 6 mg L⁻¹. The highest concentration gave best larval survival rates, 69% for chloramphenicol and 68% for erythromycin. There is no significant difference in survival with two antibiotics, but the author recommended erythromycin at 6 mg L⁻¹ (Campa-Córdova 1997).

29.8 NATURAL SPAT

29.8.1 Methods Employed

In Bahía de La Paz, different kinds of structures were built for supporting gear and for collecting spat as described by Félix-Pico (1991a). The spat collectors were suspended

from a long line held with buoys and anchors. For bottom culture, a pond was delimited with mangrove sticks and plastic nets in shallow areas. Three types of spat collectors were built; onion sacks (40 x 70 cm, 0.8-cm mesh) filled with shrubs and polypropylene nets, wood boxes filled with shells and chivato (*Atriplex* spp.) or chamizo (*Batis maritima*) shrubs, and Nestier plastic cages filled with polyfilm and shells. For rearing, the spat were placed in lantern type baskets and in Nestier plastic cages. Two hundred baskets were installed on each long line. Details of construction and specification of materials are described by Vicencio-Aguilar et al. (1988) and Vicencio-Aguilar et al. (1994).

29.8.2 Spat Collection

The timing of spawning and distribution of pectinid larvae are thought to depend upon environmental conditions. The natural spawning season was established by sampling the zooplankton each week and by installing spat collectors simultaneously. Also, the gonadal index was estimated in adult specimens, as were the number spat per collector, type of collector, spat sizes, depths, and the relationship between abiotic and biotic variables. Table 29.4 summarises the achievements in wild spat collection of *A. ventricosus* on both coasts of Baja California Sur between 1977 and 1999. Average figures of seed per collector are noticeably different. The incidence of pelagic larvae collected was associated, together with temperature at 3-m depth and number of seed per collector, with lunar phases, blooming of palo verde (*Cercidium peninsularae*), spawning season, and probable settlement period (Félix-Pico et al. 1980, 1989). A program was begun in the Gulf of California in 1977 and the Pacific lagoons in 1981. Previous results showed that 1977 settlement of pectinid spat on artificial collectors were good in Ensenada de La Paz. Monitoring of settlement continued until the population of catarina scallops declined in 1981. Results have shown great variation in number of spat per collector. From 90 to 635 scallop spat per collector were found (Félix-Pico 1991a).

Ruiz-Verdugo and Cáceres-Martínez (1990, 1991) deployed experimental collectors (25 x 25 cm, 2-mm mesh) at Bahía Falsa (Bahía de La Paz) during 1987 and 1988. Maximum spat collection occurred between 15 to 17 m depth during April to June. The range of spat collected was 85–217 per collector. For the first 5 weeks after settlement, the growth rate was 0.34 mm day⁻¹, and can be described by the linear equation:

$$\text{Shell height} = 0.2 + 0.34 * \text{days} \quad (14)$$

In Bahía Magdalena, B.C.S., Tripp-Quezada (1985) recorded from 100 to 300 spat per collector in April of 1981. Almost one year later, spat collection was more successful (up to 2,212 spat per collector) but the local scheme of abundance was somehow reversed. Results have shown that the best collecting season was between January to March when temperature had a minimum value of 19°C, and the best sites were Santa Elena and San Vicente (Estero Santo Domingo) in the northern part of Bahía Magdalena. In the south much lower numbers of spat were obtained per collector with a maximum of 100. The most efficient spat collectors were onion bags filled with plastic mesh (Tripp-Quezada

Table 29.4

Summary of wild spat collected from catarina scallops, for the period 1977 to 1999 at the aquaculture areas. (Data from Félix-Pico (1991a), Tripp-Quezada (1991), Félix-Pico et al. (1995), Ruiz-Verdugo and Cáceres-Martínez (1991), Félix-Pico et al. (1989), Tripp-Quezada (1985), Maeda-Martínez et al. (1993), Félix-Pico et al. (1997), Félix-Pico et al. (1980), Singh-Cabanillas (1987), García-Domínguez et al. (1992), Millán-Torvar (1997), Ruiz-Verdugo and Cáceres-Martínez (1990), Félix-Pico et al. (1992), Maeda-Martínez et al. (2000), Maeda-Martínez et al. (1996), Castro-Moroyoqui (1992), Félix-Pico and Villalejo-Fuerte (1999), Tobias-Sánchez and Cáceres-Martínez (1994)).

Geographical Areas, Lagoons, Sites	Years	Type of Collector	Spatfall per Collector	Season

Laguna Ojo de Liebre		Onion bags, plastic cages	1,500–8,000	Jun–Aug.
Laguna San Ignacio	1990	Onion bags, plastic cages	500	Jun–Aug.

1991). In 1989 and 1990 when the megapopulation was 750 million scallops, the spat collection pattern changed, producing a longer spat collection season, and a fourfold increase in the number of spat collected. In central Bahía Magdalena, bottom water temperature was a minimum of 14°C during April and May. From July to August, the temperature increased from 21°C to 25°C, with the major summer settlement between

10,000 to 12,000 spat per collector (Félix-Pico et al. 1992; Santamaria-Gallegos et al. 1999; Maeda-Martínez et al. 2000).

Monitoring of settlement of catarina scallop at Bahía Magdalena continued between 1989 and 1999 extending the area studied south to include Laguna Rancho Bueno. Results have shown high numbers of spat in 1990 when more than 2,000 to 6,000 spat per bag were collected (Félix-Pico et al. 1992). Up to 300 to 5,000 scallop spat per collector were found. In 1995 when the population under culture was of 3.5 million scallops, the spat settlement increased to a maximum of 10,000 scallop spat per collector during January (Maeda-Martínez et al. 1996, 2000). In recent years, lower numbers of the spat in 1999 were found with only 700 scallop spat per collector (Tizoc Moctezuma, personal communication).

Spat collection was studied at Lagunas Guerrero Negro, San Ignacio, and Ojo de Liebre in Baja California Sur; from July 1985 to August 1986. The results of 950, 680 and 500 seed per collector were found in each lagoon. The highest incidence of spat was recorded at the end of summer. It was suggested that scallops spawn when water temperature is between 20°C and 22°C (Singh-Cabanillas 1987). Monitoring of settlement of catarina scallop continued between 1989 and 1992 in Laguna Ojo de Liebre, with higher numbers of spat obtained per collector, a maximum of 353, 6,300 and 8,100 between May and July during these years. A similar result was obtained at Laguna Guerrero Negro of 2,600 to 6,300 spat per collector. In the south (Laguna San Ignacio), much lower numbers of spat were obtained per collector, a maximum of 500 (Castro-Moroyoqui 1992).

In Bahía Bacochibampo, Sonora, Reyes-Sosa (1985, 1990) plotted abundance data as the mean number of spat per collector by month and found three peaks in November, February, and May. Those peaks were followed by an abrupt decrease of settlement in the following months. The largest peak was recorded in May when 177,000 spat were collected. In 1995, the area studied was extended north into the upper Gulf of California. Attempts were made to collect juveniles from a natural set of *Argopecten ventricosus* but results were disappointing. A storm caused the loss of the culture (Carvajal-Rascón and Farrell 1984) (Douglas McLaurin, personal communication).

Singh-Cabanillas and Bojórquez-Verástica (1987) searched for commercial species for aquaculture purposes at Bahía Concepción, B.C.S. and found three species present on their collectors; *Argopecten ventricosus*, *Euvola vogdesi* and *Pinna rugosa*. Catarina scallop spat were monitored in Bahía Concepción using onion bags that were deployed, based on seasonal abundance of spat, from February 1987 to March 1994. During this period, scallop showed a high spawning intensity in March (peak), and lower spawning intensity continuing through April and May. In general, settlement was poor in the north but was good in the southern part of the bay. In 1987, the settlement resulting from a reduced winter-spring spawning (broodstock estimated at 70 million scallops) was 500 spat per bag. In 1988, the settlement increased to 40,000 spat per bag and the broodstock was estimated at 120 million. For 1991, the settlement decreased to 18,000 spat per bag and the broodstock was about 50 million scallops. For 1994, few juveniles were caught in spat-collecting operations (157 spat per bag). It was decided to stop the spat-collection program (Félix-Pico et al. 1995, 1997; Bojórquez-Verástica 1997).

Mano de león (*Nodipecten subnodosus*) in Laguna Ojo de Liebre can be a potential spat production bank. Observations on spat settlement in artificial collectors indicate that major settlement takes place during 2 months, September–October, and that the exact time of settlement varies from year to year (1990–1991) occurring from September to November. Numbers of spat per collecting onion bag varied between 4 to 74 spat per collector. Maximum spat collected occurred below 5-m depth (García-Domínguez et al. 1992). In Bahía de Loreto, Gulf of California, settlement was found on spiny shells (*Spondylus princeps*) in March and May 1994 and 1995. Adult of *N. subnodosus* spawn between December and February, indicating the major settlement takes place during a period of about 3 months. Numbers of spat per collecting shell (1–2) were relatively constant but varied with depth, ranging between 20 to 40 m (Félix-Pico and Villalejo-Fuerte 1999). Some authors reported spat settled on collectors in Bahía Concepción and Bahía de La Paz, but a low number of spat were collected there (Ruiz-Verugo and Cáceres-Martínez 1991; Bojórquez-Verástica 1997; Wright-López 1997) and at Bahía Bacochibampo, Sonora (Carvajal-Rascón 1987).

Settlement of voladora scallop (*Euvola vogdesi*) spat on experimental collectors (25 x 25 cm, 2-mm mesh) was studied from 1987 to 1988 at Bahía Falsa (Bahía de La Paz). Ruiz-Verdugo and Cáceres (1990, 1991) found maximum spat collection occurred between 7 to 17 m depth during June and July. The range of spat numbers collected was 7–21 per collector. For the first 5 weeks after settlement, growth rate was 0.29 mm day⁻¹ and can be described by the linear equation:

$$\text{Shell height} = 0.21 + 0.29 * \text{days} \quad (15)$$

Tobías-Sánchez and Cáceres-Martínez (1994) tested the feasibility of collecting spat of *Euvola vogdesi* in Bahía de La Paz. Experimental collectors were made by Vexar filament net, monofilament, plastic mesh, coconut fibre, polypropylene bands and black polyethylene. After 5 weeks at 3-m depth, the spat were recorded from April–July. The largest number of spat were collected on Vexar filament and monofilament (44% of total collected), with 274 to 468 seed per collector in April 1988. The linear equation for the first five weeks was:

$$\text{Shell height} = 0.21 + 0.35 * \text{days} \quad (16)$$

29.9 GROWTH

29.9.1 Suspended Cultures

In 1977, the scallops (*A. ventricosus*) were used in a first attempt at growout trials in suspension culture grown from wild spat. Nearly one thousand specimens were obtained in 2.5 m². In March, they had a mean size of 0.95 cm. Two hundred scallops were put into each cage. Their mean size in May had reached 2.31 cm with 45% of scallops in the large-size category. Scallops were rearranged in several lots with different densities. In August, lot I had a mean size of 36 mm with a density of 250 individuals per cage and

35% of them in the large-size category. In October, the mean size was 40 mm with 35% of scallops in the large-size category. Results in other lots were not significantly different. Lot II reached a mean of 35 mm with 30% in the large-size category at a density of 100 scallops per cage. Lot III with same density reached a mean of 34 mm with 45% in the large-size category. In lot IV the mean size was 37 mm with 200 scallops per cage. Data of the monthly increase shell length were used to determine parameters of a von Bertalanffy growth curve. Growth response at density (50 scallops per cage) was estimated as $L_{\infty} = 4.9$ cm, and $K = 0.03$ (cm per month). This year larger sizes were recorded because of a more intensive handling (i.e., more frequent changes of cages) (Félix-Pico et al. 1989; Félix-Pico 1991a). The condition index for scallops can be described by the exponential equation

$$\text{Meat weight} = 0.43 L^{11.9} \quad (17)$$

In 1979, the suspended culturing allowed a commercial-scale forecast by means of an analysis of the sensitivity in the production. Bioeconomic analysis of the catarina scallop has been made by Negrete-Martínez (1982) and Hernández-Llamas (1989). Analyses were made at low and high stocking rates. For plant sizes larger than 1.2 million juveniles, using high densities improved the internal rate of return but had a higher risk because of critical inconsistencies in survival. The internal rate of return was particularly sensitive to the maximum size attainable by the scallops, mortality, sale price and cost of equipment for growout. The importance of considering uncertainty in the variable estimates when projecting a pilot plant is addressed (Hernández-Llamas 1997).

México's first private scallop aquaculture company (Cultivos Marinos S.A.) was formed in La Paz in 1980. A local bay scallop, *Argopecten ventricosus*, was grown in lantern nets suspended from long lines. Scallops are stocked at a density of 25 scallops per 0.1 m² (50 per level) for the final growth stage. Market size (5 to 6 cm) was reached in 7 months. Four metric tons of scallops were marketed in México City in the first year of production (Siewers 1982). In 1982, when the scallop ground was overexploited, the company was closed because the collectors only caught 3 juveniles.

Tripp-Quezada (1985) reported growth for *Argopecten ventricosus* as an 11 month increase in the size expressed at San Vicente, 58.8 mm, Los Prados, 46 mm, and San Buto, 45 mm, at the northern part of Bahía Magdalena.

Reyes-Sosa (1988) reported growth for catarina scallop from Bahía de Bacoichampo experimental hanging culture for 27 weeks. The size increase was length 50 mm and total weight 35.9 g and recommended the period of culture from November to June. The growth observed on cultured scallops during 7 months can be described by the equation (Fig. 29.7):

$$\text{Shell height} = 62.36 (1 - e^{(-0.057(t + 1.95))}) \quad (18)$$

Figure 29.7. Growth curves calculated by the equations number 18 and 19, from data of suspended culture of *Argopecten ventricosus*. (From Reyes-Sosa (1988) and Hernández-Llamas and Gómez-Muñoz (1996)).

Hernández-Llamas and Gómez-Muñoz (1996) in experimental culture of catarina scallop at Ensenada de La Paz determined growth in relation to stocking density and length of culture period. In this study, a significant growth response to stocking rate was observed. In general, large sizes were produced when density decreased. The common allometric weight-length coefficients for the whole data set were estimated as $a = 0.073$ and $b = 2.93$ ($P < 0.05$). Growth response at density (50% of available area occupied) was estimated as $L_{\infty} = 4.31$ cm, $K = 0.42$ (month) and $t_0 = -0.78$ ($P < 0.005$). The von Bertalanffy growth equation (Fig. 29.7) was:

$$L_t = 4.31(1 - e^{-0.42(t - 0.78)}) \quad (19)$$

The growth rates of juvenile catarina scallops (spat from hatchery) suspended in plastic trays was evaluated at different densities in Laguna Rancho Bueno (CULTEMAR, Co.), Bahía Magdalena (Maeda-Martínez et al. 1997). Three densities were tested at each of the culture stages. The first as nursery was 1,500, 2,500 and 4,000 scallops m^{-2} for 80 days, the second phase as intermediate was 400, 700 and 1,000 scallops m^{-2} for 80 to 136 days, and as growout was 150, 250 and 400 scallops m^{-2} for 136 to 320 days. In the first two stages, growth rates were higher at low densities, but growth rates were the same at low and medium densities in the growout stage. Mean final shell heights were 5.7, 5.6 and 5.4 cm for each density. Muscle weight was affected by density, estimating a 21% reduction caused by crowding. A cost analysis indicates that, regardless of the longer

time, culturing scallops at high density would be less expensive than at low density, taking into account the muscle-weight loss caused by crowding.

An experiment to test feasibility of growing 400 juveniles originated in the laboratory of the Universidad Autónoma de Baja California in Ensenada. Scallops, *N. subnodosus*, were sown into triangular structures (100 x 40 x 50 cm) covered with a plastic mesh (8-mm opening), and suspended from a long line system off Isla Gaviota, Bahía de La Paz. The scallops reached 57-mm shell height in the first year of culture (Barrios-Ruiz et al. 1997). These results are similar to those found by García et al. (1992) for the same species in the Laguna Ojo de Liebre, where the scallops reached 58 mm in the first year of life. Some other experiments related to *N. subnodosus* report 35 mm in 107 days of culture in Bahía de La Paz (Morales-Hernández and Cáceres-Martínez 1996) and 43 mm in four months off the coast of Sonora (Carvajal-Rascón 1987). The instantaneous daily growth rate found in the experiment was 0.143 mm, which is similar to that found by García et al. (García-Domínguez et al. 1992), but is less than half found by Morales-Hernández and Cáceres-Martínez (1996), 0.327 mm, and Carvajal-Rascón (1987), 0.352 mm.

Félix-Pico and Villalejo-Fuerte (1999) in experimental culture of *N. subnodosus* at Bahía Juncalito determined growth over one year. The instantaneous daily growth rate found was 0.23 mm day⁻¹.

The voladora scallop *Euvola vogdesi* was grown to determine its growth rate using organisms 20-mm high collected in Bahía Juncalito (Loreto), Gulf of California, observing them for twelve months in conditions of extensive culture. Through the summer and autumn the growth was fastest, obtaining a mean height of 46.9 mm. In winter, the mean height was 52.4 mm, with then a steady growth to the summer (Villalejo-Fuerte and Tripp-Quezada 1997).

29.9.2 Bottom Cultures

The growth rates of juvenile *A. ventricosus* in an enclosure called a "parque" were compared at different densities. The enclosure is a stationary structure of wooden bars buried in the substrate, to which plastic or anchovy fishing nets are fixed. Juvenile scallops with mean initial height of 28 mm and weight of 5.6 g were sown at densities of 100, 500, 1,000 and 2,000 scallops m⁻² for 93 days. The average final heights were 47, 39, 32 and 30 mm, and weights were 33, 16, 9 and 7 g (Ramírez-Filippini and Cáceres-Martínez 1994). Another modular system was tested, which is based on individual modules that can be replaced for maintenance. The juveniles are sown inside the enclosures over a sand substrate and remain for 5 to months until they are harvested. The average growth is 5 to 6 mm per month using a density of 100 scallops m⁻² (Ramírez-Filippini et al. 1990; Ramírez-Filippini and Cáceres-Martínez 1994).

Maeda-Martínez et al. (2000) used a bottom-culture system (tube or sack) on a commercial level to grow *A. ventricosus* in the Rancho Bueno (CULTEMAR, Co.) tidal channel in Bahía Magdalena. The system consisted of a 50 x 1 m sleeve of 19-mm mesh polyethylene netting placed on the sea floor of selected growout areas. The bottom culture gear represents an advancement in scallop cultivation procedures, and the authors obtained a patent (No. 180211) on this system (Maeda-Martínez and Ormart-Castro

1995). A total of 448 sleeves divided into 12 lots or groups of scallops were deployed from October 1994 to April 1995. Each sleeve contained 10,000 scallops with average size 32-mm shell height. A total of 19,300 kg of meat was harvested at the end of culture (between 109 to 319 days). Mean final size was 56.2 ± 3.2 mm with a minimum of 52.4 ± 2.9 mm in 118 days and a maximum of 58.2 ± 3.7 mm in 240 days. Final adductor muscle wet weight varied from 4.4 g at 118 days to 8.5 g at 319 days. Average survival in the sleeves was $71.2 \pm 3.8\%$ with a minimum of 60.4% and maximum of 86.5%.

In Bahía Concepción during February 1993, spat were counted and measured, and a bimodal recruitment pattern obtained (1.5 cm on average). The spat settled in the bottom and samples were taken and measured each month. The dates were fitted to the von Bertalanffy equation with $L_{\infty} = 78$ mm and $K = 1.4$. These results are in agreement with previous studies in other areas (Villalejo-Fuerte 1997). On 15 June 1994, about 933,000 juvenile scallops were placed in an enclosure with a density of 330 scallops m^{-2} . The scallops were held until 10 August, when they were released. Growth was estimated by measurements of the shell length and wet weights of different body portions. The culture period was 17 weeks. The final size of the scallops was 43.7 mm, total wet weight was 24.5 g, and meat weight was 9.0 g. The weekly size increase was 1.1 mm, the wet weight increase 1.24 g, and the muscle weight increase 0.1 g. In a protected bottom culture, the growth was at 6-m depth. The culture period was 25 weeks beginning in June. Shell length growth rate was 0.65 mm $week^{-1}$, total body weight growth was 0.62 g $week^{-1}$, and adductor muscle growth was 0.07 g $week^{-1}$. Adductor muscle production was 910 g m^{-2} (Félix-Pico et al. 1997).

Bottom culture of voladora scallop *E. vogdesi* was done in plastic cages at 10-m depth by Ruiz-Verdugo and Cáceres Martínez (1994). A total of 2,300 scallops 12 to 21 mm in height were grown at 450 scallops m^{-2} during 135 days. For this period, the size increase was estimated as 57 to 60 mm. The results of growth were adjusted to Von Bertalanffy equation as:

$$L_t = 74.19 (1 - e^{-0.003(t-45)}) \quad (20)$$

29.9.3 Factors Influencing Growth

Temperature has been widely acknowledged as important in controlling growth rate. Sicard et al. (1999) found that growth of *A. ventricosus* (10–12 mm shell height) occurred between 12 and 28°C, with an optimum between 19°C and 22°C. Growth declined sharply at 28°C after 54 days of experiments. Studies of activity, ingestion and clearance rates, and the irrigation efficiency were made to obtain the optimum temperature. Results indicate that activity increased from 12°C to a maximum at 19°C, and then declined to 28°C. Mean ingestion and clearance rates were higher at 19 and 22°C and lower at 16, 25 and 28°C. Irrigation efficiency followed the same trend as activity. A similar experiment was done by Carvalho-Saucedo (1999), who determined the response of activity and standard metabolic rates to temperature, at 22°C and 28°C. The clearance rate was determined using two populations from Bahía Magdalena and Bahía Concepción, and reciprocal crosses and inbreeding lines. At the end of the experiment of clearance and

metabolic activity, there were no significant differences for both populations and the reciprocal crosses, but the standard metabolic rate was higher at 28°C. A similar result was obtained with the inbreeding lines, when they were compared to a control.

Silva-Loera (1986) found the catarina scallop had a higher metabolic rate at a comparable temperature ranges (20°C to 30°C). The temperature coefficient ($Q_{10} = K_1/K_2$ when oxygen uptake at temperatures T_1 and T_2) for oxygen consumption was 1.94 and 2.77 mL h⁻¹ g⁻¹ for scallops 1 and 0.1 g dry tissue weight, respectively.

In addition to the factors discussed above, there are probably many others that influence growth. The coastal lagoons along the Pacific coast of México are exposed to heavy rainfall and freshwater runoff, however, the Baja California Peninsula and Sonora state have hypersaline lagoons where scallop grounds are found. Signoret-Brailovsky et al. (1996) found the species is a perfect osmoconformer by exposing specimens from normal salinity (37‰) up to 57‰ and down to 17‰ at a constant 28°C. Hemolymph osmolality followed the same trend as the changing external media throughout the salinity levels tested. Survival records indicate that salinity tolerance is restricted to 27–47‰.

Cruz-Hernández et al. (2000) evaluated two different populations and their cross (F1) for the age at first sexual maturity or the effects of different native environments. In Bahía Magdalena, a site characterised by high productivity, lower average temperatures (14–27°C), and a high chlorophyll-*a* concentration (1.5–5.1 mg m⁻³). The environment conditions of Bahía Concepción are characterised by low productivity, higher average temperatures (17–32°C), and a low chlorophyll-*a* concentration (0.3–1.6 mg m⁻³). Differences between the two populations were clearly evident when grown at Bahía Magdalena but not at Bahía Concepción. At Bahía Concepción, sexual maturity was not reached by any of the groups. However, at 7 months, some mature individuals were already present for Magdalena population, but not for the Concepción population. Results suggest that a triggering mechanism exists in catarina scallop for the initiation of sexual maturation, whereas the differences between environments suggest that regardless of the mechanism, environmental conditions have a significant role in further maturation processes.

29.10 MORTALITY

29.10.1 Suspended Culture

Natural mortality estimates have been calculated (Félix-Pico et al. 1980) by counting dead scallops found in each basket and those missing in destroyed baskets. In early stages (i.e., scallops up to three months old), mortality was between 6% and 12%. The highest figures (30%–40%) were recorded in summer (August and September) when the mean size of scallops was 3.8 cm. Mortality was lower in the baskets built with synthetic net, but some were destroyed by fish (*Spheroides annulatus*, *Diodon hystrix* and *Balistes polylepis*) and the crustaceans (*Callinectes bellicosus*). Siewers (1982) using the Japanese lantern net observed a pufferfish *Spheroides annulatus* preying on cultured scallops by chewing open the bottom compartments of some of the lantern nets. Shortening the lantern net by 3 levels alleviated this.

In Bahía Bacochibampo, Sonora, Reyes-Sosa (1988) recorded the highest rates of mortality in summer by comparing different baskets having a density of 150 scallops per cage.

Tripp-Quezada (1985) studied mortality in three different structures and found no significant difference; concluding mortality was related instead to the particular area of culturing.

Hernández-Llamas and Gómez-Muñoz (1996) in experimental culture of catarina scallop at Ensenada de La Paz identified two patterns of the mortality, both during the culture period and among stocking densities. One was associated with the post-spawning period and second occurred at high densities with increased temperatures and overstocking (at 66% to 100% of occupied area).

Maeda-Martínez et al. (1997) reported 9% mortality during the 320 day experiment of culture of *A. ventricosus* and did not correlate with density. Zero mortality was recorded during the first 8 months, and then began to occur during the spawning season at the onset of summer.

Félix-Pico and Villalejo-Fuerte (1999) made an experimental culture of *N. subnodosus* at Bahía Juncalito. Variations of the shell height achieved in spring had significant consequences on survival during the subsequent summer (survival rate 75%). Mortality was caused by high temperature over 29°C. Barrios-Ruiz et al. (1997) reported a high mortality during summer at Bahía de La Paz, when the temperature reached more than 30°C. Survival at the end of the first year was about 38%.

29.10.2 Bottom Culture

The natural mortality of catarina scallop, *A. ventricosus*, was estimated from organisms cultured in an enclosure called a "parque" at different densities. Results suggested that densities of 500 and 2000 scallops m⁻² gave a declining growth rate and mortality increased. Mean final mortality was 26% and 37% at these densities (Ramírez-Filippini and Cáceres-Martínez 1994). Low densities of 40 scallops m⁻² gave 14% mortality (Cáceres-Martínez et al. 1987). Another modular system was tested based on individual modules that can be replaced during maintenance. The juveniles are sown inside the enclosures at a density of 100 scallops per m² and remained 7 months. The mortality was estimated at 15% by the end of the culture period (Ramírez-Filippini et al. 1990; Ramírez-Filippini and Cáceres-Martínez 1994).

An experimental culture was developed, using a 25 m² surface mesh cage. A total of 2,000 catarina scallops of 30 to 40 mm in height were placed at 75 scallops/ m² for 60 days. For this period, a natural mortality about 10% was estimated (López-Contreras and Cáceres-Martínez 1994).

Maeda-Martínez et al. (2000) using a tube system had a mean survival of 71%. Survival figures are low when compared with results in suspension culture (>90%) and were probably caused by the escape of scallops when the sleeves were cast into the growing area.

Villalejo-Fuerte (1997) estimated a natural mortality $M = 1.6$ of catarina scallop spat when they were released on the bottom without protection at Bahía Concepción. Félix-

Pico et al. (1997) using an enclosure, had a mass mortality of scallops in September, with more than 80% mortality, increasing to 99% in October. The final survival was only 1%. The possible causes of mortality were heavy predation and high water temperatures of 29°C to 33°C. The final density was 3 scallops m⁻². When other methods was used, bottom cages with light plastic frame, the final survival was 40%, with a final density of 300 scallops m⁻².

Ruiz-Verdugo and Cáceres-Martínez (1994) used a bottom-cage system for *E. vogdesi* in Bahía de La Paz. Mean final survival was 6% to 10% after 135 days. A similar result was obtained, with mortality of 68% during the summer (Cáceres-Martínez et al. 1989).

29.11 CONSTRAINTS

Natural Seed Collection. Scallop supplies are erratic and usually insufficient from the natural stocks. Relatively little work has been done with these species, although it is known that spawning can be induced and larvae of some scallops can be raised to adult size.

Hatchery Production. Pilot testing of laboratory procedures is required to improved technology for rearing cultured *Euvola vogdesi* during the early life cycle stages.

Transporting Spat. Maeda-Martínez et al. (2000) tested the feasibility of transporting seed to growout areas. Spat were placed in sandwich layers of wet sponge and plywood lids inside vinyl bags, with these packed in styrofoam coolers with ice. Results indicated that seed can be successfully shipped out of water over long periods of time (>37 h). The highest survival was 98% at 17°C.

Disease. In aquaculture there so many disease problems that the use of bacteria as probiotics is gaining in importance as an alternative to antibiotics. There is some available information about probiotics in aquaculture.

Production and Cost. The economic analyses are also insufficient (Negrete-Martínez 1982; Hernández-Llamas 1997). Montaña and Pérez (1988) showed project finances and programming. Maeda-Martínez et al. (2000) determined the economic yield of the bottom culture system. The storage, processing, marketing, value, and future prospects are included in fishery charts.

29.12 FUTURE PROSPECTS

The decline of the commercial pectinid fishery in Baja California Sur, because of multiple factors, has given an impetus to the development of a scallop cultivation industry. The growth of this new industry has been slow. The reasons for this slow growth range from the difficulties of securing prime oceanfront sites for hatchery and growout operations at reasonable costs, to regulatory constraints, and to the lack of research and development funds. Considerable progress has been made in scallop cultivation practices, particularly in the areas of broodstock management, spawning induction, larval rearing, and growout. Further refinements are needed, principally in area of nutrition, genetics and diseases.

Chapter 30

**Scallop Fisheries, Mariculture and
Enhancement in Australia**

Mike Dredge

30.1 INTRODUCTION

At least 50 species of scallop have been described from Australian coastal waters (Lamprell and Whitehead 1992), although the taxonomy of many is confused and contradictory. There are, however, appreciable fisheries directed towards only two of these species. These are a trawl fishery for saucer scallops, *Amusium balloti*, in tropical and sub-tropical waters off Queensland and Western Australia, and a dredge fishery for commercial scallops, *Pecten fumatus*, in temperate waters off Victoria, Tasmania and, rarely, off New South Wales.

Pecten fumatus was originally described as three species - (*Notavola alba* (Tate) in Victorian waters, *N. meridionalis* (Tate) off Tasmania, and *N. fumatus* (Reeve) off New South Wales, but Woodburn (1990) identified these taxa as a single species on the basis of electrophoretic data. A separate species, *Pecten modestus*, occurs along the southern and south-western coasts of Western Australia. *Amusium balloti* was classified as *A. japonicum balloti* in its Queensland distribution, but the Western Australian distribution of the species was not recognised or referred to by Habe (1964). Until the taxonomy of the species is further investigated, the species will be referred to as *A. balloti* throughout its Australian distribution.

Queen scallops, (*Equichlamys bifrons*) and doughboys (*Mimachlamys asperima*) are taken as a byproduct or minor component of southern Australian fisheries. *Pecten modestus*, the Western Australian equivalent of the commercial scallop, has supported intermittent commercial fishing operations off the south-west Western Australia coastline and the mud scallop *Amusium pleuronectes* is sometimes taken in small quantities by Queensland and Northern Australian trawlers. There are minor commercial and recreational dive fisheries for *P. fumatus* and *P. modestus* in South Australia, Victoria and Western Australia. Dive and dredge fishing are permitted in Tasmania's recreational scallop fishery (Anonymous 2000).

Australia's scallop fisheries have produced an average of 3,000 tonnes of meat, with a landed value of approximately Au \$60m annually, which represents about 4% of Australia's total commercial fisheries production value (Caton and McLoughlin 2000).

Managers and resource users of all Australian fisheries, including those for scallops, have become increasingly aware of sustainability issues and the environmental impacts of fisheries. This awareness is partly attributable to legislative requirements. Most Australian fisheries statutes require fisheries to conform to the principals of ecologically

sustainable development. Changes to Australian Commonwealth legislation, under the *Environmental Protection and Biodiversity Conservation Act 2000* that will effectively prohibit export of products from fisheries that cannot demonstrate target species sustainability, ecological sustainability and negligible impact on endangered and threatened species, are creating substantial changes in the way that Australian fisheries are currently being assessed and managed.

This review will describe the biology, fisheries, management and mariculture potential of *P. fumatus* and *A. balloti*, and the social environment in which the fisheries exist.

30.2 HISTORY OF THE FISHERIES

The Australian scallop fishery for *P. fumatus* commenced in Tasmania's Derwent River estuary and D'Entrecasteaux Channel (Fig. 30.1) in the early to mid 1910's and peaked in the latter area in 1962, when production was in the order of 550 tonnes of meat (Table 30.1, Fig. 30.2). During the fishery's early development, an unrecorded but appreciable proportion of the catch consisted of doughboy scallop (*Mimachlamys asperimus*) (Fairbridge 1953). The D'Entrecasteaux Channel population collapsed in about 1965, and appears not to have recovered since then (Harrison 1965, Young and Martin 1989, Zacharin 1990a). Vessels moved from the Channel to scallop beds that were discovered along the eastern Tasmanian coast over a period of 10–15 years. There appears to have been a history of the coastal Tasmanian grounds being serially depleted and not recovering for extended periods, if at all (Young et al. 1990). The Tasmanian fleet first fished grounds in Bass Straits in the early 1970's, following successful survey work undertaken by staff from Tasmania's Department of Fisheries (Grant and Alexander 1973). Catches from the Bass Strait grounds have varied considerably since the fishery commenced, although catches in recent years have been taken from relatively small areas in the south-eastern areas of the Strait. Proportions of the Bass Strait catch landed in Victorian and Tasmanian ports can no longer be separated.

The combination of reduced Tasmanian catches, growing Australian markets and increased publicity about the existence of a scallop resource in Port Phillip Bay (Victoria) led to an explosive growth of fishing operations in this area. Upward of 300 vessels, many from Tasmania, joined the fishery between 1963 and 1966 (Sanders 1970). Production exceeded 2,000 tonnes of meat in the peak production years of 1966 and 1967. The Port Phillip Bay scallop population declined in 1969 and much of the fleet moved to newly discovered beds off Lakes Entrance and other areas in Bass Strait. The Lakes Entrance and Bass Strait fisheries have persisted since that time, despite having to cope with irregular recruitment and intermittent closures caused by recruitment failure. The Port Phillip Bay fishery was closed in 1996, in response to community and political concerns about the impact of the fishery on benthic habitat and recreational fisheries resources (McCormack and McLoughlin 1999).

Figure 30.2. Annual production of *Pecten fumatus* in Australia.

The trawl fishery for *A. balloti* commenced in the mid 1950's off the central Queensland coast, between 23°S and 25°S (Ruello 1975), and in the early 1960's in Shark Bay (25°S–26°S), off the Western Australian coast (Harris et al. 1999) (Fig. 30.1). Both began as secondary operations to existing prawn fisheries but have since become substantial fisheries in their own right. The fisheries benefited and expanded when meat quality was recognised on international markets. The bulk of the Australian *A. balloti* catch is now exported to markets in southeast Asia. A number of the trawlers that fish for *A. balloti* in Shark Bay also work in the vicinity of the Abrolhos Islands (28°S), and, occasionally, in waters south and west of Perth (32°S–34°S), where recruitment is far less consistent than in Shark Bay. While more than 90% of average annual landings from the Queensland fishery have been taken between 23°S and 25°S, grounds in the vicinity of Hydrographer's Passage (22°S) receive intermittent recruitment and occasionally produce substantial quantities of saucer scallops (Fig. 30.1).

30.3 BIOLOGY OF TARGET SPECIES

30.3.1 *Pecten fumatus*

30.3.1.1 Distribution and life cycle

Pecten fumatus has been recorded along the southern and eastern Australian coastline between western South Australia (133°E) and central New South Wales (30°S) (Woodburn 1990). *Pecten modestus* occurs in waters off southern and southwestern Western Australian, and a form of *Pecten*, described as *Pecten jacobaeus byronensis* (perhaps in error) by Fleming (1955), recruits intermittently in waters off southern Queensland and northern New South Wales.

Pecten fumatus is a functional hermaphrodite that normally spawns in winter and spring (June to November) in Tasmanian and Victorian waters (Harrison 1961; Sause et al. 1987a; Young et al. 1999), and in late winter and early spring towards the northern limits of its distribution (Jacobs 1983). The species normally attains sexual maturity in its second year. Under hatchery conditions, the species has a 10–12 day larval phase (Dix and Sjardin 1975). There have been a number of studies directed towards understanding the timing of larval settlement in the species' natural environment, particularly in the context of predicting recruitment levels (Hortle and Cropp 1987; Sause et al. 1987b; Coleman 1990; Young et al. 1992). These studies have shown that maximum larval settlement onto spat collectors typically occurs in spring and early summer.

Hortle and Cropp (1987) and Sause et al. (1987b) recorded spat growth of 6–10 mm month⁻¹. Growth rates of juveniles and adults have been described by Fairbridge (1953), Sanders (1970), and Dix (1981), using tagging, shell check interpretation and size frequency analysis. These studies indicate that there is considerable variation in growth rates, with an average size of 30–40 mm shell length (maximum diameter) being attained in the first year, but in some circumstances attaining 60 mm in a year (Sause et al. 1987b). *Pecten fumatus* typically attains 70–80 mm in the second year of life and has an average maximum shell length (von Bertalanffy's L_{∞}) of 86–93 mm. There is some evidence of a change in the species' growth rates in its Port Phillip Bay distribution (Gwyther and McShane 1988), with growth rates increasing appreciably in a 20-year period. Whilst populations of *P. fumatus* including up to 16 year classes were recorded in the fishery's early history (Fairbridge 1953), the fishery is now almost entirely dependent upon 2+ and 3+ year old animals (McLoughlin 1994), which has caused concern about the potential for recruitment overfishing.

30.3.1.2 Mortality

While there have been a number of studies on predators and parasites that might cause mortalities to *P. fumatus*, there appears to be only one detailed study of population natural mortality rates for the species. Gwyther and McShane (1988) reported an annual instantaneous natural mortality rate (M) of 0.52, which is equivalent to an annual survival rate of approximately 60%. Starfish (*Costinasterias calamaria*) and whelks (*Fasciola australasia*) were reportedly responsible for the death of as much as 80% of a scallop population in the D'Entrecasteaux Channel, in southern Tasmania, over a four year period (Olsen 1955). A number of parasites, including mudworm (*Polydora websteri*) (Dix 1981), bucephalid trematodes (Sanders and Lester 1981) and nematodes (McShane and Lester 1984) have been reported to cause mortality of *P. fumatus* but the impact of these species on population levels have not been determined.

Population levels of *P. fumatus* in Port Phillip Bay were at historically near-low levels in 1999, despite the termination of the commercial fishery in 1996 (Coleman, pers. comm.). There is evidence that interactions between a number of introduced species, particularly the clam *Corbula gibba*, which is now very abundant in Port Phillip Bay, may be responsible for a decline in scallop abundance (Currie and Parry 1999, Talman and Keough 2001).

30.3.1.3 Monitoring, abundance and population dynamics

Population levels and population status of *P. fumatus* are monitored largely through fisheries statistics. Data on landings, effort distribution and catch rates for catches made in state waters are collected and collated by fisheries management agencies in Tasmania and Victoria, and by the Australian Fisheries Management Authority (AFMA), for catches made in the central, Commonwealth managed, zone of Bass Strait. Data are sourced from daily or monthly fisher returns. AFMA produces an annual assessment report (Caton and McLoughlin 2000), which includes a summary on the state of the Bass Strait scallop population, but the respective state authorities do not currently produce population models or assessment reports other than the production of fishery data as annual catch and effort summaries.

The Tasmanian Government authorises annual exploratory fishing operations by licensed scallop boats. Results from operations carried out by these boats are used to determine whether or not the fishery is opened in Tasmanian waters.

Although the Victorian State Government does not conduct stock assessments on scallops in Bass Strait, annual recruitment surveys and population assessments using diver observations were conducted in Port Phillip Bay in the period 1982 to 1996 (Coleman 1998), prior to the fishery's closure in this area. Survey data were used to estimate total population numbers and have served as catch predictors in the Port Phillip Bay area. The surveys demonstrated that recruitment variation within the Bay was considerable. High recruitment levels did not invariably lead to successful fishing seasons, as juvenile populations occasionally suffered high mortality levels. While the annual survey was discontinued in 1996, it has been repeated irregularly since then. The exceptionally low recruitment levels recorded in 1999, in the absence of commercial fishing, (Coleman, pers. comm.), may be a consequence of competition from exotic benthic organisms.

Sporic et al. (1997) attempted to relate commercial scallop recruitment and meat condition to environmental parameters, including nutrient and trace element levels, chlorophyll levels and coarser measures such as river flows, salinity and water temperatures. Whilst adductor condition of scallops could be related to some of the variables used in analysis (often on a time lagged basis), the only environmental variable correlated to catch rate was water temperature. The authors concluded that there was little scope for predicting scallop catches on the basis of environmental parameters. Recruitment and population levels in waters administered by the Victorian Government are now monitored through exploratory fishing operations. The results of these surveys are used to determine when and where fisheries for scallops are allowed.

Total catch data (Table 30.1, Fig. 30.2), which are the only readily available, comprehensive and long-term information series on the population of *P. fumatus*, do not reflect the true state of the population. Rather, they reflect a complex series of fish-down events, some of which occurred over many years (as in the D'Entrecasteaux Channel), discoveries of new beds, and irregular recruitment in areas such as Port Phillip Bay and the Bass Strait (Young et al. 1990). Caton and McLoughlin (2000) describe the species as being over-exploited. While detailed population models are not available, the general trends of effort distribution and total catch data support this conclusion.

30.3.2 *Amusium balloti*

30.3.2.1 *Distribution and life cycle*

Amusium balloti is a predominantly sub-tropical species that occurs in water depths of 15–50 m, typically between 18°S and 25°S along the Queensland continental shelf (Dredge 1988). Outliers have been recorded as far south as Jervis Bay (35°S), in New South Wales (Smith 1991). The species' Western Australian distribution extends between 18°S and 35°S (Harris et al. 1999).

The species is gonochoristic and normally spawns in winter and spring (Dredge 1981, Joll and Caputi 1995a). It has a 12–25 day larval phase under hatchery conditions, with settlement of post larvae occurring at a size of approximately 200 µm. There is no evidence of more than a very transient byssal phase (Rose et al. 1988, Cropp 1994). This implies that conventional spat catching techniques are unlikely to collect *Amusium* spat. This observation is consistent with findings reported by Sumpton et al. (1990) and Robins-Troeger and Dredge (1993) in their studies on scallop spat collection in areas where *A. balloti* normally occurs. Successful settlement appears to create aggregations or beds of scallops. The only such beds that have been examined in detail were oblong in shape, with the longer axis lying parallel to the direction of tidal flow (Dredge 1985a).

Amusium balloti is characterised by exceptionally rapid growth. Joll (1988) has described the formation of daily growth rings in the Western Australian population of the species, and described growth rates of up to 2.2 mm week⁻¹. Williams and Dredge (1981) and Dredge (1985a) reported von Bertalanffy parameters for *k* (instantaneous growth rate) in the range 0.052–0.059 week⁻¹ and *L*_∞ in the range 101–108 mm, using both tagging and sequential size frequency composition data. These growth rate parameters imply the species can attain a shell height of 90 mm in 6–12 months. While maximum lifespan may be 3 years, the bulk of the fished population consists of 0+ and 1+ animals (Dredge 1994, Harris et al. 1999). The species is processed in roe-off form, and the adductor meat displays seasonal variation in condition, which has significant implications in terms of yield optimisation.

30.3.2.2 *Mortality*

Amusium balloti has the relatively high natural mortality rate consistent with a short-lived species. The only published report on natural mortality rates for *A. balloti* in its normal distribution estimated the instantaneous rate for *M* of 0.02–0.025 week⁻¹ for scallops in the size range 50–110 mm (Dredge 1985b). This is equivalent to an annual mortality rate of approximately 60% for scallops in this size range. There are no data available on natural mortality rates of juvenile saucer scallops. Studies of predators and parasites that may be responsible for natural mortality are limited. Jones (1988) described the scyllarid lobster *Thenus orientalis* as a predator of *A. balloti*. Other known predators include octopus, a number of turtle species and the sparid *Pagrus auratus* (Harris et al. 1999). There have been no comprehensive studies on the parasitology of *A. balloti*, but the species is known to act as the intermediate host for an ascaroid nematode, *Sulcascaris*

sulcata, which uses loggerhead turtles, *Caretta caretta* as a final host (Berry and Cannon 1981). There are no data on the impact of this species on survival rates of *A. balloti*. The top shell *Capulus dilatata* parasitises *A. balloti* after boring into the shell, but its impact upon population levels is again unknown.

30.3.2.3 Monitoring, abundance and population dynamics

The major *A. balloti* resources of Western Australia and Queensland are monitored and assessed by means of annual recruitment surveys and review of commercial catch and effort data collected by fishers. Each state fisheries authority conducts a comprehensive annual survey to monitor recruitment levels and provide predictions of subsequent stock levels available to the fishery. Reviews of catch, effort and trends in both fisheries are published in annual or irregular fisheries status reports (Penn 2000; Williams 2002).

Annual landings from the Western Australian fishery are strongly correlated with recruitment levels as estimated through the annual survey (Joll and Caputi 1995b), and annual catch predictions are now offered on the basis of this survey (Penn 2000). The main determinant of recruitment levels in the Western Australian population appears to be prevailing environmental conditions driven by the el Nino – Southern Oscillation (ENSO) phenomenon. This, in turn, is thought to be related to the behaviour of the Leeuwin current system off the Western Australian coastline, although the exact mechanism driving recruitment levels remains unknown (Joll 1994; Caputi and Joll 1995b). Recruitment and catch levels were an order of magnitude greater than the long term average in 1991–1993, years in which the ENSO event had major impacts on water movements and temperatures off the Western Australian coastline (Table 30.2, Fig. 30.3). There appears to be no definable relationship between parent stock size and subsequent recruitment levels in the Western Australian population of *A. balloti*.

The Queensland fishery for *A. balloti* appears to exploit the resource far more heavily than is the case for the Western Australian population. There have been concerns about potential recruitment overfishing (Dredge 1988; Dichmont et al. 1999), which have led to the introduction of precautionary management measures, including spatial closures to maintain spawner levels. Population assessments for the Queensland stock of *A. balloti* are now based upon reviews of commercial catch and effort data and information derived from an annual recruitment survey conducted in October each year (Dichmont et al. 2000). The recruitment survey has been conducted for three years and is not yet capable of giving meaningful predictions of annual landings. Dichmont et al. (1999) have developed models to examine the status of the Queensland saucer scallop resource, but their value as a management tool or predictor for landings has not yet been tested.

30.4 FISHERIES AND THEIR MANAGEMENT

30.4.1 *Pecten fumatus*

30.4.1.1 Regulation

The major Australian fishery for *P. fumatus* is most readily described in terms of a single fishery managed by three jurisdictions. The Victorian Government is responsible for the species to a distance approximately 20 n. miles seaward of the Victorian shoreline. Tasmania has responsibility for management of scallop fisheries south of a line established under Australia's Offshore Constitutional Settlement that follows Latitude 40°45'S to about 144°E, and then approximately 20 n. miles seaward of the northern

Figure 30.3. Annual production of *Amusium balloti* in Queensland and Western Australia.

Tasmanian coastline. The Commonwealth of Australia is responsible for fishing operations in the area between the two jurisdictions (Fig. 30.1). These arrangements can be linked to the fishery's history. The fisheries originated in coastal waters of Tasmania and Victoria, and moved to the oceanic waters of Bass Strait, the fisheries of which have historically been managed by a Commonwealth agency. Arrangements under which the three agencies co-manage the resource were formalised in 1986.

All three management agencies dealing with the major *P. fumatus* population in Victorian, Tasmanian and Bass Strait waters have had to deal with "boom and bust" fisheries that have attracted excess fishing capacity during boom years.

Managers administer the fishery in accordance with the objectives and requirements of three statutes, the Commonwealth Fisheries Management Act 1991, the Tasmanian Living Marine Resources Act 1995, and the Victorian Fisheries Act 1995. These statutes have some similarities in that they require sustainable use of fisheries resources amongst other objectives based on social and economic imperatives. All three jurisdictions have imposed limited entry into scallop fisheries, and many of the boats involved in the fishery have access rights to all three administrative zones.

While there has been no clear demonstration of a stock-recruitment relationship in the species, Young et al. (1990) presents limited data in support of the concept that spat settling in given areas of Bass Strait may originate from concentrations of spawners in the same areas. Depletion of spawners from such areas could therefore lead to localised recruitment failure. Managers in all three management areas support a policy of allowing

scallops to spawn twice before being harvested, in order to minimise the risk of recruitment overfishing (McLoughlin 1994). In years of low recruitment, fisheries management agencies have closed the fisheries.

Tasmanian government policy on scallop resources now only allows for the harvesting scallops when there are adequate stock levels, at a time and size that will allow yield to be optimised (Anonymous 2000). The fishery has been closed for 6 of the past 10 years in Tasmanian waters, due to low recruitment levels. Consequently, the fishery has become a secondary operation for the 117 vessels that currently hold licenses to fish for scallops. All vessels that are so licensed have access to other fisheries and fish for scallops irregularly.

The fishery operates on the basis of marketing a roe-on product, both to local and European markets, and is administered to maximise yield and value by allowing only winter – spring fishing, when gonads are at peak condition. Environmental impacts of the fishery are managed by prohibiting scallop dredging in sensitive shallow areas, by limiting dredge numbers and by requiring the use of dredges that minimise impact on the seabed.

The Victorian scallop fishery's management arrangements have been profoundly affected by the legislated closure of Port Phillip Bay to scallop dredging in 1996. The fishery was permanently closed on the basis of social and ecological arguments, following jurisdictional procedures that had important implications for the nature of property rights in Australian fisheries (McCormack and McLoughlin 1999). The Victorian fishery is now restricted to coastal and oceanic waters to the south of the state, with an appreciable proportion of the state's landing being taken from Commonwealth-managed waters and, intermittently, from Tasmanian waters. Ninety-four operators are licensed to take scallops in Victorian and adjacent Commonwealth-managed waters. Vessels are allocated annual quotas that vary with available stock levels. The quotas, which are transferable, are further regulated on a monthly basis (currently ca. 3 tonnes, whole animal weight) to ensure an orderly supply of product to processing facilities and markets. The season is subject to seasonal closures that allow scallops to be taken in the period May-October, when the animals are in optimal condition.

Additional to this fishery, a minor fishery for *P. fumatus* in South Australian waters is managed as a limited entry dive fishery. The fishery currently includes only 4 licensed operators who have produced insignificant amounts of scallop in the past 10 years. The highly intermittent New South Wales and Western Australian *Pecten* fisheries have been managed on an "as-needs" basis in the past. Concerns about the impact of dredging on benthic communities may restrict use of these resources should future recruitment be sufficient to stimulate commercial interest.

30.4.1.2 Environmental management and sustainability issues

There have been detailed studies of the impact of scallop dredging, particularly in Port Phillip Bay. Currie and Parry (1996, 1999) concluded that dredging had a clearly detectable effect on benthic fauna and topography in the short term, but longer term impacts were far less noticeable. Following the closure of the Port Phillip Bay scallop

fishery, environmental management issues were largely directed to the impact of the fishery on the target species. In addition to the 'two spawning' rule, scallop fishing is not allowed when a pre-determined proportion of the catch is smaller than the prevailing size limit in order to minimise wastage. Reducing the impact of scallop fishing on associated benthic communities has been considered in the context of using physically less impacting catch gear (Zacharin 1990b) but still remains a major issue for the industry to address.

30.4.2 *Amusium balloti*

30.4.2.1 Regulation

There are marked differences between the management of saucer scallop (*A. balloti*) fisheries in Western Australia and Queensland.

The Western Australian fishery occurs in spatially discrete areas near Shark Bay, off the Abrolhos Islands and, intermittently, to the west and south of Perth. Each area is managed as a separate entity. The collective fishery is managed under a basic tenet that the residual stock levels should not be fished below a level required to maintain long-term recruitment levels despite the absence of any apparent relationship between breeding stock levels and recruitment. Consequently, management of the fishery has been largely focused towards maximising yield, maintaining economic efficiency and minimising conflict with other fisheries that occur in the same locations. This is achieved through limited entry and seasonal closures (Harris et al. 1999). As all product is shucked at sea size limits are not a feasible option for yield optimisation. Entry to the Shark Bay fishery is restricted, with a total of 41 trawlers being authorised to take saucer scallops in this area. Of these, 27 are also entitled to take penaeid prawns and consequently fish for saucer scallops on a part time basis. The saucer scallop fishery is seasonal, with a regulated opening normally occurring in April - May and the season closing in November to coincide with the seasonal closure of a major prawn fishery. In reality, the saucer scallop fishery normally ceases well before November as numbers decline to economically unviable levels. The Abrolhos fishery is likewise subject to restricted entry and a seasonal fishery regime. Recruitment in this area is far less consistent than in the Shark Bay area, and most of the 16 trawlers that are licensed to fish in this area have access to alternative fisheries. A restricted entry fleet of four trawlers fishes saucer scallops that recruit intermittently on grounds off the state's southern coastline, typically off Esperance, and three trawlers are licensed to take scallops and other trawlable species in grounds west of Perth (34°). Effort in all these fishing grounds is constrained by vessel dimensions and trawl gear size, with trawl size being restricted to a maximum of nets with headrope length no greater than 18 m.

Saucer scallops taken in the Western Australian fishery are shucked as roe-off meat and frozen at sea. Almost all product produced by the fishery is exported, mostly to south-east Asia, where the market offers premium prices for saucer scallop meat (Hart 1994).

The Queensland fishery for saucer scallops is managed as an element of the Queensland East Coast trawl fishery. This complex fishery is largely directed towards the

capture of 9 species of penaeid prawn, but also takes crabs, scyllarid lobsters and fish as byproduct, in addition to an average 1100 tonnes of scallop meat a year (Table 30.2, Fig. 30.3). While entry to the composite fishery is limited and boat numbers are being reduced, there are still more than 700 licensed trawlers that fish along the eastern Queensland seaboard between about 10°S and 28°S. All of these boats have access to the saucer scallop resource, but only 200–300 trawlers report landing scallops in any one year.

The resource is fished heavily. Management procedures are aimed both at yield optimisation and minimising the risk of recruitment overfishing. A seasonally varying size limit and a late winter-early spring closure are used to maximise yield (Dredge 1994). Trawl gear size is limited to a maximum 109 m of (combined) headrope and footrope in order to constrain effort, and three 10'×10' areas that have historically held high densities of saucer scallops have been closed to fishing as a means of maintaining spawner population levels. Saucer scallops are required to be processed ashore, or in a number of designated inshore shucking areas, in order that size limits can be policed.

The bulk of Queensland's saucer scallop production is exported, again largely to south-east Asian markets (Hart 1994).

The marked difference between the Queensland and Western Australian entry policies for saucer scallop fisheries reflect the fundamentally different approaches taken by fisheries managers during the development of Australian trawl fisheries in the 1960's and 1970's. Western Australian managers took a highly precautionary attitude, focused on species-specific management and were committed to a philosophy of developing profitable, flexible fisheries that could fully meet monitoring and management requirements (Hancock 1975). Queensland managers adopted a much more open market philosophy that eventually lead to Queensland becoming a 'dumping ground' for trawlers from a number of other Australian jurisdictions. At one point in time almost 2,000 trawlers were authorised to fish in Queensland waters (Hill and Pashen 1986). There has been a slow reduction of trawler numbers, but the fishery still has excess fishing effort.

30.4.2.2 Environmental management and sustainability issues

Both the Western Australian and Queensland saucer scallop fisheries have taken action in recognition of environmental management and conservation issues.

The Queensland scallop fishery is administered under a trawl fisheries management plan that is subsidiary legislation to the State's Fisheries Act. This plan includes trigger points for management intervention, based upon prescribed declines in catch rates of the target species. It includes a number of conservation measures, including limitations on ground chain size, compulsory use of turtle excluding devices, and the (temporary) closure of broodstock protection areas to ensure population levels are maintained. There is a requirement for reduction in bycatch levels, again with associated limit reference points, and a requirement for the fishery to have minimal impact on threatened and endangered species.

Western Australian fisheries also operate under management plans that are subsidiary to that State's Fisheries Act. These plans are essentially a set of rules for the fishery's

operation. They allow a high degree of flexibility for management responses to changing conditions in the fishery. Bycatch action plans designed to minimise impacts on non-target species are in the process of being developed. More general regional environmental management plans for the fishery are also in the process of being finalised.

30.5 CULTURE OF SCALLOPS IN AUSTRALIA

While there has been intermittent interest in the culture of scallops in Australian waters, serious commitment to development of mariculture and marine ranching has been limited.

30.5.1 *Pecten fumatus*

The first recorded investigations into the culture of scallops began in 1917, in Tasmania, when a committee was appointed to inquire into the depletion of scallop beds in the Derwent River estuary (Flynn 1918). The potential for mid-water culture was recognised by this committee, as were the predation problems caused by starfish and crabs. There appears, however, to have been no serious attempt to carry out any form of enhancement until the mid 1970's, when the Tasmanian government established a program designed to assess the feasibility of reseeded depleted scallop beds.

The Victorian, South Australian and New South Wales Governments have invested in pilot studies on the feasibility of scallop mariculture or enhancement. Projects will be described on a state by state basis.

30.5.1.1 *Tasmania*

30.5.1.1.1 *Spat production*

The feasibility of developing cage culture and enhancement operations using both hatchery reared and wild-caught spat was investigated during the course of a program commenced in 1975. Dix and Sjardin (1975) reported successful rearing of larvae through to settlement, and their techniques were successfully applied to other scallop species (Dix 1976, Rose and Dix 1984). Whilst hatchery experience and competence have been developed to the point that commercial oyster and abalone operations rely on their output, there is currently no hatchery producing scallop spat at commercial levels (Crawford, Tasmanian Scallops Pty Ltd., pers. comm.). Spat collection rates in mesh bag collectors placed off the Tasmanian east coast were initially very low (Dix 1981; Hortle 1983), but improved with time and experience to reach up to 400 spat per collector (Hortle and Cropp 1987).

30.5.1.1.2 *Culture operations*

The Tasmanian Government entered into a joint-venture agreement with the Japanese Overseas Fisheries Foundation in 1986. Under this agreement, the Japanese organisation

supplied technical expertise and capital for scallop mariculture, while the Tasmanian government provided research capacity, infrastructure, staff resources and an exclusive lease area in and adjacent to the Great Oyster Bay (Fig. 30.1). Thompson (1990) gives a brief account of the joint venture's progress.

The joint venture initially used open water spat catching techniques to obtain spat, and followed well described procedures of hanging cage culture for rearing spat, using cage culture and intermediate culture techniques as described by Ventilla (1982). The operations were not immediately successful. Short falls in spat supply and cage fouling was reported to be major constraints to growth and economic production of scallops.

The operation changed organisational structure and direction, being largely taken over by a Japanese consortium and moving towards an open water seeding operation. Open water seeding had limited success, as spat supply from both open water collectors and hatcheries was limited to between 5 and 20 million spat per year, and natural mortality rates appear to have been very high. Annual production has not exceeded 50 tonnes. Following further restructure, the operating company is now re-directing efforts towards hanging cage culture, and is investigating the feasibility of mariculture for other molluscan species, as spat supply continues to be a limiting factor for scallop culture.

30.5.1.2 Victoria

While there has been intermittent interest in the potential of cage culture within the protected waters of Port Phillip Bay, there has been little serious commitment of money or material to such operations. Spat catchers were deployed in the Bay during the 1980's as a means of monitoring spatfall for predictive fishing models (Coleman 1990). Mercer (Victorian Marine and Freshwater Institute, pers. comm.) has renewed spat collection in a pilot project to assess the potential for supplying a scallop aquaculture industry in the Bay. He obtained catches of up to 400 spat per bag in areas of eastern Port Phillip Bay in 1998 and 1999. An existing mussel farming operation has at least some of the infrastructure requirements for scallop culture work in Port Phillip Bay. Progress of this work to a pilot scale operation will depend upon State Government policy development in relation to the desirability of mariculture operations in what is regarded as an environmentally and socially sensitive area.

30.5.1.3 New South Wales

Pecten fumatus intermittently settles in large numbers along the southern coast of New South Wales. Short-lived fisheries in areas such as Jervis Bay (Fuentes 1994) have occurred as a consequence of these settlements.

There has been some interest in establishing whether the population could be stabilised through enhancement procedures, using hatchery-reared spat. There has been considerable progress in developing hatchery procedures for mass rearing of *P. fumatus* spat in hatcheries (Heasman et al. 1994; Heasman et al. 1998), but there has been little progress towards the development of a commercial cage culture or enhancement. An early (pilot) attempt to establish a bottom seeding program was unsuccessful, with

predators, including rays, causing substantial losses to the stocked out population. Concerns about the environmental consequences of dredging seeded scallops may limit future restocking operations.

30.5.1.4 South Australia

There have been two commercial attempts to develop *Pecten* mariculture operations in Southern Australian waters. Both occurred in the period between 1996 and 2000, and were based on the concept of using spat collected from open waters in cage culture operations, in waters to the north of Kangaroo Island. Little has been documented about either operation, but the initial attempt apparently closed following two seasons of unacceptably low spat collection (Young, pers. comm.). An attempt to revive this operation is in an early stage of development.

30.5.2 *Amusium balloti*

The rapid growth rate and high market value of *A. balloti* suggests the species has inherent potential for mariculture and enhancement operations. There has been some research but little commercial commitment to translate this potential to reality. The apparent absence of anything more than a transient byssal attachment in this species (Robins-Troeger and Dredge 1993; Cropp 1994) limits the scope for wild spat collection. Consequentially any fisheries enhancement or mariculture operation would be reliant on hatchery reared spat.

Rose et al. (1988) reported on initial attempts to develop hatchery techniques for breeding *A. balloti* under controlled conditions, and Cropp (1992, 1994) attempted to expand on this work to develop an operational model for saucer scallop enhancement in Western Australian waters. While his work was not immediately productive in a commercial sense, there have been further attempts to enhance saucer scallop populations using hatchery-reared spat. The Western Australian government have granted an exclusive-access seabed lease in coastal waters at about 29°S, inshore of Abrolhos Islands, and a private venture company has established a hatchery as part of a program to generate a commercial bottom seeding operation (Joll, pers. comm.). There appears to be some scope for companies currently raising pearl oyster (*Pinctada maxima*) spat to diversify into *Amusium* culture should the present program achieves commercial success.

30.6 SUMMARY

Australian fisheries for scallops have been based on two species groupings and the fisheries that have evolved from these two resources have taken very different paths. The southern Australian dredge fishery for *Pecten* spp. has gone through the 'booms and busts' that appear to characterise many scallop fisheries. This fishery, however, appears to face difficulties and challenges of unprecedented magnitude. Recruitment in some previously productive areas has failed for an extended period of time, and the fishery has been based on scallop populations with a much reduced age structure than has been the

case in historical times. Some parts of the fishery have been closed to meet social and environmental requirements, and the surviving elements still face major challenges in meeting the stringent environmental and sustainability standards associated with Australia's recently developed fisheries management standards.

The trawl fisheries for *A. balloti*, on the other hand, have been far more stable in terms of landings. Apart from the three years of massive landings from Western Australia when environmental conditions apparently improved recruitment, and a marked decline in Queensland in 1996, possibly associated with overfishing, annual landings have remained relatively stable by the standards of most scallop fisheries. These fisheries still need to address environmental sustainability issues, but have gone some way to meet these requirements.

By global standards, aquaculture and enhancement operations in Australia have received little commitment and met with little success to this time.

ACKNOWLEDGMENTS

While not wishing to ignore the help given to me by a great many friends and colleagues – too numerous to be named – I must specifically acknowledge the help of Lindsay Joll and Nic Caputi in Western Australia, Hilary Revill in Tasmania, Noel Coleman, Greg Parry and David Molloy in Victoria, Mike Heasman in New South Wales, and staff from Southern Fisheries Centre at Deception Bay, who have suffered endless talks on scallops and then had to review the written end product. Kate Yeomans put much of the art work together. My thanks to you all.

Chapter 31

New Zealand

Islay D. Marsden and Michael F. Bull[†]

31.1 INTRODUCTION

At least 18 different species of Pectinidae have been recorded from New Zealand waters (Powell 1979). Of these, only two (*Pecten novaezelandiae* and *Chlamys delicatula*) are large enough or occur at sufficient density to have encouraged any commercial exploitation. A fishery for *P. novaezelandiae* has been in existence for over 40 years and production from this fishery has averaged 660 tonnes meat weight (approx. 5,280 tonnes green or live weight) per annum between 1994 and 2002. Fishing for *Chlamys delicatula* on the other hand was carried out on an experimental basis in the late 1980's. However, because of its small size (60–70 mm) and deep water habitat (80–200 m) it did not develop into a significant fishery. This chapter has therefore been restricted to a discussion of the biology, fishery and aquaculture of *P. novaezelandiae*.

31.2 BIOLOGY

31.2.1 Morphology

Pecten novaezelandiae has the typical asymmetric shape of the genus with convex right valve and flat or slightly concave left valve and is also typical in being a functional hermaphrodite with separate male and female sections of the gonad. The shell is usually white, sometimes tinted with pink or brown and both valves are strongly ribbed with rib numbers ranging from 17–22 per valve. It is very similar in appearance to *P. fumatus* of Southern Australia but electrophoretic studies of protein similarities support its status as a separate species (Woodburn 1990).

31.2.2 Distribution

The species occurs sporadically around the whole New Zealand coastline including Stewart Island (Fig. 31.1) and the Chatham Islands (44°S, 176°W). It is found on a wide variety of substrates in semi-estuarine and coastal waters from low tide to depths of up to 60 m (up to 90 m at Chatham Islands). Individuals can be clumped in patches of conspecifics (McKinnon 1992; Morrisson 1999) but they are not associated exclusively with any single bottom community (Bull 1976). The main commercial beds at the northern tip of the South Island (Challenger fishery) occur in an open bay situation in 10–25 m on a soft muddy substrate while on the majority of North Island beds the substrate is

Figure 31.1. Commercial scallop grounds in New Zealand. Solid lines define the commercial fishing regions.

predominantly (hard) shell gravel and coarse sand (Morrisson 1999).

31.2.3 Life Cycle

The life cycle of *Pecten novaezelandiae* is similar to that of other members of the genus. Juveniles usually become mature at the end of their first year but probably contribute little to the spawning pool until the end of their second year. Fecundity is very high (15–50 million eggs/female) and variability in mortality of larvae and pre-recruits leads to great fluctuations in annual recruitment.

Observation of recently spent adults, presence of *P. novaezelandiae* larvae in plankton samples and records of spat settlement on artificial collectors indicate that in the area of the Challenger fishery some scallops spawn from August to April. In the Coromandel fishery Morrisson (1999) reported two highly synchronised spawning events in late October and mid January with some spawning in between. Fertilisation is external and larvae are thought to remain in the plankton for approximately 3–4 weeks (Bull 1976), based on a comparison with other temperate species.

Spat settlement in the Challenger area is usually highest from November to January and the data available for other areas of the country suggest a peak of settlement in early summer is probably widespread (Nicholson 1978; Bull 1980; McKinnon 1992; Morrisson 1999). At metamorphosis, late stage larvae (220 µm, Bull 1976) attach by byssus threads to filamentous material such as *Zostera* debris, algae and hydroids on the seabed and can also be caught on artificial collectors such as synthetic rope and mesh. This attachment is usually retained until the spat are at least 5 mm in shell length although smaller spat are sometimes found free living on the seabed. Juvenile scallops (2–9 mm) are quite mobile making post settlement movements by swimming or drifting at speeds equivalent to several hundreds of body lengths per second. In contrast, adult scallops are fairly sedentary and studies by Morrisson (1999) recorded movements of less than 10 m over a 14-month period from tagged individuals.

31.2.4 Growth Rates

Studies of size frequencies and measurement of tagged scallops indicate growth rates to be very variable among populations in different areas and among different depths in the same area and among different years. In the Challenger fishery area it is estimated that the majority of scallops reach 100 mm in length about 2.5 years after settlement. Large scallops in excess of 160 mm are occasionally taken but these are probably the result of especially rapid growth rather than extreme old age. Hauraki Gulf scallops reach 100 mm length in 18 months whereas scallops from the Coromandel Peninsula may take 3 years. Generally scallops grow faster in the Northland than the Coromandel fishery (Table 31.1) and the average size is larger further north. In contrast scallops from Paterson Inlet, Stewart Island have high longevity (6–7 years), and reach a larger maximal shell length, up to 170 mm (McKinnon 1992).

31.2.5 Mortality

The longevity of *P. novaezelandiae* in the wild is uncertain as is not possible to age scallops from rings on the shells (Bull 1976). In the Challenger fishery area, however, strong year classes are usually only traceable for three or four years suggesting relatively high rates of natural mortality. This ties in with estimates of the natural mortality rate obtained for the area from analysis of clucker ratios and tagging studies, which have ranged from 21% to 46% per year (Bull 1976; Bull and Drummond 1994). While rates of this order may be the norm, incidents of mass mortality have been reported on numerous occasions both in the Challenger and North Island fisheries (Table 31.2, Morrison 1999).

Table 31.1

Growth (estimated annual increments) from tagging and other studies in the Coromandel and Northland scallop fisheries (Cryer 1999) for scallops with initial shell lengths of 40 mm and 95 mm.

Growth increment	40 mm	95 mm
All data (1992–1997)	51.4	11.1
Coromandel (1992–1997)	49.9	10.3
Whitianga (1982, 1983, 1984)	52.4, 47.5, 30.3	13.8, 9.1, 6.0
Whitianga (depth 10.6 m)	60.1	15.1
Whitianga (depth 29.7 m)	31.2	6.8
Northland (1992–1977)	52.8	11.7
Bream Bay (depth 18.4 m)	53.0	8.8
Bream Bay (depth 21.4 m)	50.7	11.4

Potential causes of mortality include disease, predation, dredging, and environmental factors including storms, algal blooms, reduced salinity and excessive silt levels (Teaioro 1999). Histological examination (TEM) of tissue from wild and cultured, apparently diseased, specimens revealed virus-like particles associated with the digestive gland epithelium (Hine and Wesney 1997). Although the cytology changes were similar to those associated with enteroviruses and calciviruses, it could not be concluded that these caused the disease in the scallops. More recently, Hine and Diggles (2002) reported intracellular prokaryote infections in the digestive diverticular epithelial cells and branchial cells of both *P. novaezelandiae* and *C. delicatula*. Other potentially damaging parasites and commensals include the copepod *Pseudomyicola spinosus*, which is abundant in and around the stomach in some scallop populations, and the polychaete *Polydora hoplura*, which bores through the shell leading to weakening of the attachment of the adductor muscle. A tubellarian rhabdocoel *Paravortex* sp. has been reported from within the intestine of cultured scallops showing gaping and poor swimming ability (Woods and Hayden 1998). During the summer of 1999–2000, many poor condition shellfish, including scallops were collected from the Coromandel. This “black gill” condition was investigated histologically and bacteriologically but no bacteria were isolated and there was no indication that the tissues had been damaged by bacteria, parasites or viruses (Smith and Diggles 1999). It was suggested that this condition may have been the result of low upwelling nitrate levels over winter, warm high salinity water on the outer continental shelf, together with la Nina weather patterns..

The main predators of *P. novaezelandiae* appear to be starfish (especially *Coscinasterias calamaria*), fish including eagle rays (*Myliobatus tenuicaudatus*), snapper (*Chrysophrys auratus*) and blue cod (*Parapercis colias*), and octopus (*Octopus maorum*). In many countries, crabs are a common predator of scallops but although the voracious paddle crab *Ovalipes catharus* is abundant along the sandy margins of such areas as Golden Bay, it is not commonly found on the scallop grounds further out. Hermit crabs are, however, abundant on some parts of the fishery and they are probably predators of small scallops as

Table 31.2

Mortality estimates for *P. novaezelandiae* from different parts of New Zealand, the method used to determine the estimate; Z, instantaneous mortality, which includes fishing mortality and M, natural mortality.

Locality	Method		Estimate y^{-1}	Reference
Coromandel	Density	M	0.45–0.50	Walshe 1984
Coromandel	Density	Z	1.06, 1.09	Osborne 1990
Challenger	Cluckers	M	0.29, 0.49	Bull 1976
Challenger	Tagging	M	0.21, 0.46	Bull and Drummond 1994
Hauraki Gulf				
Ti Point	Density	Z	3–11.15	Morrisson 1999
Omaha	Density	M	1.10–2.63	Morrisson 1999
Omaha (algal bloom)	Density	M	4.66	Morrisson 1999
Pukenihini Pt	Density	M	9.56–10.59	Morrisson 1999
Motuketekete	Density	Z	1.15	Morrisson 1999
Motuketekete	Tagging	Z	1.16	Morrisson 1999

seeding of young spat in areas where the crabs are abundant has usually been unsuccessful.

While fishing is likely to be the major cause of mortality in some areas, dredging activity can significantly affect scallop mortality and cause habitat disturbance (Thrush et al. 1995). Cryer and Morrison (1997) tested three designs of scallop dredge and found that despite the high incidental mortality, the current box dredge was best for the Coromandel scallop fishery because of its higher catching efficiency.

Scallops are thought to be sensitive to environmental factors such as turbidity and suspended silt that can result from dredging, bottom trawling, storms and run-off. Stevens (1987) reported that small *P. novaezelandiae* (20 mm shell height) rapidly expel water from the mantle cavity or swim when subjected to high silt levels then, after 30 min, settle with their valves open. Mortality (LD_{50}) occurred within 7–13 h and increased with increasing silt concentration (0.05–6% dry wt) and decreasing silt particle size.

In addition, anecdotal evidence from the North Island suggests that toxic algal blooms may have affected scallop recruitment and juvenile recruitment in the past. However, there have been no reported incidents of deaths of adult scallops due to harmful algal blooms. Commercial scallops are tested weekly for marine biotoxins and to date there has only been one precautionary closure of the fishery, which was due to low levels of ASP toxins in the roe. Suzuki et al. (2001) have investigated DSP toxins comparing the pectenotoxin profiles of scallops (*P. novaezelandiae*) with that of the toxic dinoflagellate *Dinophysis acuta* in the Marlborough Sounds. The results suggest that the New Zealand scallop has the ability to reduce the cytotoxicity of the pectenotoxin (PTX) found in *D. acuta* (PTX2) by conversion to a less toxic form (PTX2SA).

31.3 COMMERCIAL FISHING

Commercial fishing for scallops in New Zealand currently occurs in three main areas (Fig. 31.1): the Challenger fishery, previously known as the southern scallop fishery (Golden Bay, Tasman Bay and the Marlborough Sounds), the Coromandel fishery (= the Bay of Plenty and the Hauraki Gulf) and the Northland fishery (= Bream Bay to Spirits Bay). In 1997, landings totalled 519 tonnes meat weight with the three areas contributing 57.4%, 26.2% and 16.4%, respectively.

In 1988 commercial fishing also began at the Chatham Islands 850 km east of the New Zealand mainland and in that year 121 tonnes meat weight was landed. However, in the following year landings dropped severely and subsequent landings have been less than 50 tonnes per annum (Bull 1990).

31.4 DEVELOPMENT OF THE SCALLOP FISHERY

The scallop fishery in New Zealand began with an experimental dredging operation in Tasman Bay in 1959. Over the following ten years boat numbers gradually increased to 26 vessels and dredging operations spread to cover grounds in nearby Golden Bay and the Marlborough Sounds.

Production from the Challenger fishery reached a peak of about 1,200 t meat weight in 1975 from a fleet of 190 vessels. In 1976 there were 245 vessels but over the following five years the fishery suffered a dramatic decline (Table 31.3) and in 1981 and 1982 the whole fishery area was completely closed to fishing. Stocks have since recovered and the Challenger fishery in 1994/1995 season harvested 850 t meat weight.

Fishing in the Coromandel and Northland areas began in the early 1970's and the catches over the following ten years showed somewhat more stable production levels than the Challenger fishery (Table 31.3). From the mid 1980's the landings were recorded as meat weight (adductor muscle and roe), which reflects the commercial value. In recent years, these fisheries have yielded over 200 tons meat weight per annum but there have been significant declines over the past two years. Between 1995 and 1997, the Northland Fishery and Coromandel Fishery together contributed at times up to 47% of the total NZ catch.

31.4.1 Capture Methods

The commercial fishery for *P. novaezelandiae* is entirely a dredge fishery with the fleet currently consisting of about 100 vessels most of which are in the 12–20 m length range. Because of the relatively short season length (2–7 months) nearly all these vessels are involved with some other fishing activity for part of the year such as trawling, gill netting, long lining or rock lobster fishing.

Scallop fishing, however, generally provides 50% or more of these fishermen's income. Most vessels are privately owned and are run by a skipper and one or two crew. The type of dredge used depends largely on the substrate of the grounds concerned. In the Challenger fishery, where soft muddy substrate predominates and where scallop densities

Table 31.3

Landings (tonnes meat weight) from NZ scallop fisheries 1970–1999. Early records are based on estimates using the gazetted conversion factor from live weight to meat weight.

Season	Marlborough Sounds	Tasman and Golden Bays	Total Challenger	Northland	Coromandel controlled

From: King (1985), King and McKoy (1984), Annala (1994), Cryer (2000), Drummond (pers. comm.), Sylvester (pers. comm.).

are often quite low (<1 per 5 m^2), most vessels use two ring bag dredges up to 2.4 m in width with heavy tickler chains. On the hard sand of North Island beds a self-tipping “box” dredge with rigid tooth bar is more common.

The duration of dredge tows is largely dependent on the amount of scallops or other material being caught but is commonly about 30 minutes. On recovering the dredge, legal size scallops are sorted from the catch and undersized scallops and shell returned to the sea. Marketable scallops are landed on a daily basis and trucked to nearby processing facilities where they are hand-shucked. Only the adductor muscle and gonad are retained and the shell and viscera are usually dumped. Meat weight recoveries are generally 12–20% of total weight with individual meats weighing 10–25 g of which the gonad may account for up to 30% or more. After shucking, the meats are usually chilled, frozen in layer packs or free flow form, although some are further processed to a crumbed or battered form. The local market currently consumes approximately half the catch with the remainder going to a variety of markets including France, Australia and USA. The quantity and destination of exports is very dependent on availability and demand and in some years, New Zealand has imported scallops from Japan and Australia.

31.5 MANAGEMENT

31.5.1 The Challenger Fishery

This fishery was one of the most highly Government regulated fisheries in New Zealand. Within the first ten years of its existence, controls had been introduced establishing a minimum size (4", later 100 mm), restrictions on number and size of dredges and an annual five months closed season (February to July).

In the late 1970's, strict controls were placed on boat numbers (245 reduced to 136) through the introduction of non transferable licenses under the Controlled Fisheries legislation and in the next 10 years controls including day light only and five day fishing weeks, daily quotas and shortened season lengths were introduced. In addition annual preseason stock assessment surveys were carried out and an upper limit on seasonal catch imposed by way of either competitive TAC's (1979 and 1980), short season length and daily catch limits (1983–1985) or individual seasonal allocations (1986–1991). These regulations were primarily aimed at prevention of biological overfishing, maximising the long-term economic return from the fishery and providing some stability for participants in the fishery.

In 1983, a three year trial on the feasibility of enhancing the fishery through the release of naturally-occurring spat caught on artificial collectors was set up. These initial seeding trials were successful and the first seeded scallops were harvested in 1986 (Clement and Bull 1988; Bull 1994). Funds generated from sale of crop from the trial seedings were used to keep the enhancement programme going for the next two years, but by 1989 an agreement had been made with the licence holders to fund seeding operations through a levy on annual catch and since that time the continuing enhancement operations in the fishery have been fully industry funded.

In 1989, in association with the development of the successful seeding operation, a switch was also made to the management system for the catching operation. A rotational system was set up in which the grounds in Golden Bay and Tasman Bay were divided into 9 sectors, with an agreed number of these sectors being opened for commercial fishing each year, followed by seeding and subsequent closure until seeded stock had reached takeable size. Under this system, in any given year, adequate stocks of potential spawners could be protected in the closed sectors and therefore there was little need to conserve spawning stock in the open sectors. Previous measures aimed at such protection such as a strict size limit and annual quotas could therefore be relaxed. As a result, the previous minimum size of 100 mm was dropped to 90 mm for the commercial fleet (= approximately the minimum size for marketing) and annual quotas were now used for allocation rather than stock conservation purposes.

In 1992, the fishery was introduced into the Quota Management System (QMS) system with 10% of the available take being allocated to Maori and the remainder being divided equally between the 48 licence holders. Between 1992 and 1995 there was a reorganisation of responsibilities resulting in a shift from Government agencies to the private sector (Arbuckle and Drummond 2000). Maori were granted an additional 10% of quota. Also, quota holdings were changed from being expressed as a set tonnage to proportional holdings so that the benefits of any increased production resulting from Industry funded enhancement and management initiatives would be returned directly to Industry.

In 1994 the Challenger Company consisting of all the quota holders in the fishery was incorporated and given the responsibility of providing a plan for enhancement, collecting research information and providing advice on management. Since 1996 there have been further management measures introduced: a compulsory levy on scallop quota holders, a daily catch balancing system and a dockside monitoring programme with penalties for exceeding the limit. In addition, Challenger Company could exclude vessels if yields were low or in the case of a biotoxin event. The Company commissioned a purpose designed enhancement vessel and has increased research effort aimed at improving the success of seeding and management of the fishery. Although there is a defined fishing season, this can be delayed to allow scallops to reach a better size before collection. However, the rules for an extended season still include an overall total allowable catch of 720 t, restricted fishing zones and biological and effort controls. In 2000 the delayed start to dredging together with variability in scallop size resulted in a lower than usual catch (Table 31.3).

31.5.2 The Northland and Coromandel Scallop Fisheries

The Northland fishery consisted of 38 vessels up until 1997 when it was introduced into the Quota Management System (QMS). The number of vessels has since declined (Cryer 1999) and the Northland Scallop Enhancement Company includes 33 quota holders. The main commercial beds used to be Bream Bay and bays approximately 110 km to the north. However, in 1994, beds in the Spirits Bay area at the tip of the North Island were opened up and since then, this area has contributed more than 50% of the

Northland catch. Destruction of other benthic species by dredging in this area (especially sponges, hydroids and bryozoans) has however been of concern and a significant part of the grounds has subsequently been closed to scallop fishing.

The Coromandel fishery was a controlled fishery with 22 licence holders before it was included into the QMS in 2002. As with the Northland fishery there have been marked fluctuations in productivity among different beds over the years and yield from the fishery is currently at a very low level. Management controls on the fishery include controls on seasonal catch (based preseason surveys), on dredge size, fishing hours, non-fishing days and voluntary closed areas. In 1995 the previous minimum size of 100 mm was reduced to 90 mm in exchange for a package, which included further closed areas and reduced catch limits in an attempt to address concerns about the impacts of dredging on juvenile scallops.

31.6 RECREATIONAL FISHING

There is intense interest in non-commercial scallop fishing throughout New Zealand by recreational fishers. Scallops are taken by SCUBA diving and the use of small dredges and in a few areas by intertidal collections. Scallop divers are required by law to measure and count the shellfish on the seabed. They are not permitted to do this on the boat. Divers that fail to follow these rules could have their vessels confiscated. Daily bag limits vary among areas depending on scallop availability and recreational fishing pressure. At present, they are 10 per person per day in Southland, 50 per person in the Challenger area and 20 per day in the other 3 Fishery Management Areas. Because of depleted stocks, shellfish dredging was prohibited inside Paterson in 2003 and there is a temporary ban on collecting or possessing scallops until 30th September 2007. There are limited data on the extent of the recreation catch. Bradford (1997) estimated recreational take made up 20% of the total take from the Coromandel fishery and 5% for the Northland fishery in the 1994/95 season.

In the Challenger Fishery recreational fishers have access to both wild stocks and those seeded by the commercial industry but are not confined to the rotational zones that the commercial fishers are restricted to. Again, the extent of recreational take for this fishery is uncertain, although a national diary survey conducted by the Ministry of Agriculture and Fisheries gave an estimate of only 22 tonnes (= 3% of the take) for the area in the 1992/93 season.

31.7 AQUACULTURE AND ENHANCEMENT

In the late 1970's and early 1980's there was considerable local interest in farming scallops using Japanese hanging culture techniques and a number of small scale trials were carried out. While collection of spat in Japanese type spat collectors proved relatively easy, attempts at on-growing scallops using Japanese pearl net, lantern cage and ear hanging systems were plagued by fouling especially by mussels (*Perna canaliculus*) and also by unexpected mortality. Because of these problems, and relatively high costs of equipment and labour in New Zealand, it was concluded quite early on that scallops

operations based on Japanese hanging culture techniques were unlikely to be economic in New Zealand (Cameron 1983). More recent attempts at scallop culture have suffered from the same problems and interest in such ventures appears to have now declined, especially as they would have to compete with the success of scallop enhancement operations in the Challenger fishery and the booming New Zealand mussel industry.

In addition to the early hanging culture trials, trials on the feasibility of enhancing scallop production by seeding the spat caught in collector bags onto the seabed were begun in 1982. In 1983, the New Zealand Ministry of Agriculture and Fisheries, in conjunction with the Overseas Fisheries Cooperation Foundation of Japan expanded this work and embarked on a three year pilot scale trial in Golden Bay (Challenger area). In its first year, the catch in the 44,000 collectors resulted in a release of approximately 35 million spat three to four months after settlement. A similar scale operation was carried out in the second and third years.

Follow-up work on the seeding trials indicated that rates of survival to harvest could be in excess of 20%. It also became apparent that survival of spat that settled on the outside of the collector bags and eventually released themselves naturally onto the seabed was quite high. Further these spat could also be used for seeding by dredging them from the seabed and redistributing them when they reached a suitable size (>25 mm).

On completion of the three year trial, the spat catching and seeding operations were expanded as quickly as possible leading to an estimated release in 1992 of more than 1 billion spat from collector bags and 204 million individuals transplanted from the seabed at the spat catching site (Bradford-Grieve 1994). Although survival rates for spat seeded in such large quantities has often been much lower than that found in the original seeding trials, research has shown that up to 80% of the commercial catch comes from seeded individuals (Annala 1994). The seeding operations are now an integral part of the management of the Challenger scallop fishery (Bull 1994).

Following the success of the enhancement trials in the Challenger area in the mid 1980's, similar trials were conducted in the Coromandel fishery and small scale spat catching trials have also been made in the Northland fishery (Morrisson 1999) and at the Chatham Islands. Catches in excess of 500 spat per collector bag were made in the Coromandel trials but subsequent survival of spat released onto the seabed was negligible. This was possibly due to extreme weather conditions at the time of release in the first year and heavy predation by fish on the clean sandy substratum at the release site chosen in the second year (Bartrom 1989).

31.8 FUTURE DEVELOPMENTS

In the Challenger scallop fishery it seems likely that there will be a gradual increase in yield and improved stability of the resource as seeding operations are refined and the seeding area is expanded to cover the Marlborough Sounds section of the fishery. In recent years, the Challenger Scallop Enhancement Company has placed more emphasis on spat survival and quality rather than the size of the spat catch. They have also moved to reduce the risk of spat fall failure by targeting more than a single period for spat collection.

In the Coromandel and Northland areas, increasing demand for amateur only fishing zones as the recreational fishing population expands is likely to lead to a long-term decline in the commercial fisheries in those areas. The shift to the QMS system in the Northland fishery and the success of self-management as shown by the Challenger Scallop Enhancement Company has improved the chances of an enhancement operation being established in that area. However, the feasibility of catching sufficient spat within the Northland fishery on a regular basis has yet to be demonstrated, as has the likely hood of an adequate survival rate of seeded spat. There are significant differences in substrate type and associated fauna between the Northland and Challenger scallop grounds and factors influencing survival are likely to be quite different between the two areas.

Potential threats to the industry are the apparently increasing incidence of toxic algal blooms in New Zealand waters and sporadic outbreaks of unexplainable shellfish disease. There are demands by conservationists for increased areas of coastal marine reserves and establishment of non-dredging zones. Finally, there is increasing pressure from other sectors of the marine industry for permits to farm within the Challenger fishery area.

ACKNOWLEDGMENTS

We would like to thank members the scallop industry who shared with us their knowledge and provided access to unpublished reports. Thanks especially to Kim Drummond, Martin Cryer, Graeme McGregor, Martin Workman, Todd Sylvester and Russell Mincher. Mike Bull died in May 2002 and IDM would like to thank Sue Lindsay (Mike's widow) for her support in the publication of this chapter.

Pectenophilus ornatus, 599-600, 633-634, 646-647
Perkinsus qugwadi, 600, 615-616, 639-640, 983, 985
Perkinsus karlssoni, 597, 615-617, 642, 645, 650
Perkinsus marinus, 647
Perna canaliculus, 1422
Pfiesteria piscicida, 450, 452, 488
Pfiesteria shumwayae, 450, 452
Phaeodactylum tricornutum, 102, 1158, 1363
Phyllobotrium, 1354
Phyllonotus erythrostomus, 1353
Pilumnus caribbaeus, 1331
Pinnotheres concharum, 1353
Pinnotheres maculatus, 597-598, 632, 643
Pinnotheres sinensis, 1151
Placopecten, 1-2, 4, 6-7, 17, 19-21, 31-32, 55, 58, 74, 79, 85, 92, 95-97, 104, 242, 251, 254-262, 273, 310, 337, 340, 469, 666, 690, 709, 770, 835, 912, 919, 927
Placopecten decemnarius, 20
Placopecten grandis, 407
Placopecten magellanicus, 1-2, 6, 11, 17, 19-20, 49, 53, 58, 62, 77, 80, 82, 88, 91, 93, 95-97, 100, 106, 108-111, 114-117, 120, 125-131, 135, 137, 139-149, 151-152, 154, 157, 159-160, 163, 167-170, 173, 176, 184, 188, 190-191, 195, 199-201, 203-205, 208, 212-213, 215, 218-222, 224-227, 229-231, 235, 238-241, 244, 248, 253, 255, 261-262, 271-272, 274, 280, 294, 302, 310-311, 314, 340, 343, 353, 355, 360, 364, 366-373, 375-376, 378, 384-388, 391, 393, 396, 403, 407-418, 420-421, 425-428, 432-443, 445-446, 448-449, 451, 454-460, 462-472, 474-492, 494, 496, 498-502, 504-513, 515-516, 518-519, 526, 531-532, 537, 539-540, 542, 545-546, 554, 557-560, 564-565, 568-569, 571-573, 575-576, 580, 583-590, 592, 594, 602, 607-613, 622, 624-625, 628, 630-632, 635, 637, 639, 641-643, 647-652, 655, 657, 659, 666-667, 669-670, 673-679, 685, 687, 690-696, 699, 701-703, 705-706, 709-710, 715-716, 718-740, 742, 744, 747, 749-755, 758-764, 770, 772, 774, 776, 780-783, 794, 796, 806, 813-815, 818-819, 823-824, 826, 831, 833, 837, 841-843, 845-847, 849-850, 852-859, 861-866, 869-870, 881-882, 898-905, 907, 909, 912-913, 917, 920, 927, 930-947, 1006, 1033, 1037, 1040, 1042, 1044, 1065, 1230, 1232, 1238, 1246
Placopecten meridionalis, 603, 630
Placopecten princepoides, 19-20, 44
Plagiogramma interruptus, 418
Planorbis contortus, 458, 477
Platymonas subcordiformis, 1158
Plesiomonas, 1190
Pleurosigma, 418
Polydora, 598, 600-602, 608, 611, 629-632, 639, 646, 648-649, 960, 1000, 1051, 1082, 1088, 1151, 1188, 1251, 1353, 1416
Polydora ciliata, 630-631, 1188
Polydora concharum, 611, 630-631
Polydora socialis, 630
Polydora variegata, 600, 630-631
Polydora websteri, 598, 600, 602-603, 630-631, 639, 1188, 1251, 1285, 1396
Proctoeces maculatus, 624
Propeamussium centobi, 46, 49
Propeamussium imbriferum, 51
Propeamussium groenlandicum, 51
Prorocentrum compressum, 1352
Prorocentrum lima, 450, 452, 475, 927
Prorocentrum mexicanum, 1352
Prorocentrum minimum, 452
Prorocentrum micans, 1352

Protothaca laciniata, 626
Protothaca staminea, 626
Prymnesium, 448, 450, 491
Pseudamussium, 17-19, 21, 31-32, 38, 44, 49, 54
Pseudamussium clavatum, 49
Pseudamussium septemradiatum, 17, 19
Pseudentolium, 12, 14, 30
Pseudentolium corneoides, 12
Pseudentolium corneum, 12
Pseudohinnites, 46, 49, 109
Pseudohinnites levii, 49
Pseudoisochrysis paradoxa, 439, 1360
Pseudoklossia pectinis, 601, 617, 644
Pseudomonas, 103, 113, 600, 605-606, 645, 959, 1189-1190, 1350
Pseudostylochus orientalis, 983
Pseudostylochus ostreophagus, 600

R

Rhizosolenia, 1343
Rhizosolenia chunii, 450, 453, 486
Rhizosolenia delicatula, 450, 453, 1061

S

Scrobicularia plana, 218
Serripecten, 15-16, 30
Serripecten tiorioriensis, 15
Similipecten similes, 49
Spondylus tenebrosus, 49
Stereochinus agassizi, 1272
Swiftopecten swifti, 2, 46, 49, 581, 1164, 1215, 1221

T

Tapes decussatus, 211, 536, 606
Tetraselmis, 102, 398, 401, 436, 441, 523, 1304, 1323, 1359, 1380
Tetraselmis chunii, 523, 1323
Thalassiosira, 102, 221, 418, 426, 428, 450, 1273
Thalassiosira pseudonana, 426, 429, 435-436, 1304, 1360, 1363

Tridacna squamosa, 56, 113
Tubularia larynx, 110
Tumidotheres margarita, 1353, 1382

 Aquaculture, 42, 104-106, 108-113, 115-121, 176, 210, 212, 216-218, 224, 226, 229, 300, 316, 358, 401, 406-408, 412-413, 415-416, 451, 476, 478, 480-490, 492-493, 520, 537-543, 549, 558, 563, 566, 571, 579-584, 586-593, 595, 637-643, 645-648, 650, 694, 706, 714-715, 718-719, 721-724, 726-727, 729-737, 739-742, 761-763, 773, 775, 836, 842, 844-847, 850-857, 859-863, 901-902, 905, 907-909, 913, 924-925, 929-945, 958-959, 961-964, 966, 975, 979-980, 984-989, 1009, 1026, 1035-1044, 1046-1061, 1064-1067, 1076, 1079, 1084, 1086-1091, 1094, 1106-1107, 1114, 1122-1123, 1125-1126, 1133, 1136, 1138-1141, 1143-1144, 1151-1155, 1161, 1163, 1189, 1196, 1213, 1217, 1222-1223, 1225-1230, 1232-1233, 1237-1240, 1242-1247, 1249-1251, 1263, 1268, 1283, 1287-1288, 1290-1291, 1293, 1295-1301, 1307, 1310, 1312-1314, 1322, 1332-1334, 1337-1338, 1350, 1352, 1357-1358, 1370-1371, 1373, 1379-1385, 1387-1390, 1406, 1408, 1410, 1413, 1422, 1424
 Aquaculture development, 642, 930, 1059, 1067, 1086, 1225, 1243, 1300, 1350
 Artificial aquaculture systems, 491

Artificial diets, 427, 442, 482, 527, 530, 538
 Assimilation, 88, 158, 179, 399, 474, 477, 479-480, 490, 498, 516, 518, 746, 1104, 1359
 ATP hydrolysis, 275, 289, 312-313, 316
 Auricles, 11-15, 17-21, 23, 25-26, 124-125, 161-163, 165-167, 170-171, 225, 335-337, 344, 349-350, 692, 694, 696, 907, 922, 974-976, 1146, 1152, 1230, 1319-1320

B

Bacteria, 45, 88, 99, 102-104, 118, 120, 122, 152, 170, 224, 422-423, 488, 526, 552, 596-598, 600-602, 605-607, 610-612, 621, 623, 636, 638, 640, 642, 645, 647-650, 910, 1090, 1189-1190, 1207, 1239, 1245, 1304, 1322, 1350, 1368, 1379, 1416
 Barium, 759
 Barnacles, 465, 638, 867, 959, 976, 1075, 1118, 1151, 1164, 1202, 1330
 Benthic boundary layer, 445-446, 479-480, 695, 724, 751, 762, 788, 851, 994
 Bioaccumulation, 175, 745-746, 756, 760-763, 1013, 1037, 1050
 Bioassay tests, 101
 Biodeposits, 757, 1205, 1207, 1211, 1218-1219
 Bioindicators, 756
 Biomagnification, 748, 750, 762
 Biomarkers, 757, 759
 Bitumen, 749-750, 760
 Black scallop, 414, 458, 477, 496, 503, 517, 519, 563, 581, 738, 863, 1036, 1041, 1055, 1065
 Blood, 124, 141, 160, 162, 165, 214, 226, 464, 466, 593, 600, 619, 634, 1154, 1246
 Blood chemistry, 225, 415
 Blood vessels, 130-131, 135, 162
 Bonferroni correction, 559-560, 569-570

Bottom culture, 470, 474, 482, 647, 706, 710, 712, 737, 794, 907-908, 922-923, 925-926, 929, 931, 938, 999, 1062-1063, 1077, 1200, 1238, 1243-1244, 1320, 1322, 1326-1327, 1330-1332, 1334, 1354, 1358, 1369, 1375-1376, 1378-1379, 1385

Brooding species, 51, 99

Broodstock, 357-358, 374, 401, 403, 411, 489, 521, 526, 528-529, 533, 536, 539-541, 549, 577-578, 588, 601, 606, 614, 618, 635, 641-642, 828, 855, 896, 909, 939, 942, 982, 1060, 1078, 1080, 1112, 1157, 1235, 1242, 1301, 1303, 1305, 1358-1360, 1368, 1371, 1379, 1404

Broodstock diet, 107, 528-529, 537, 1086

Brown tides, 447-448, 476-477, 480, 482, 489-490, 636, 642, 648, 842, 950, 960-961, 964

Bryozans, 1118

Butterfly scallop, 978

Bycatch, 804, 888-889, 893, 896, 899, 978, 1057, 1281, 1284, 1404-1405

Byssal attachment, 444, 452, 679-680, 684, 689, 692-693, 742, 883, 999, 1070, 1255, 1257, 1331, 1407

Byssal gland, 207-208

Byssal notch, 12-15, 17-21, 23, 207, 210, 922, 1011, 1099, 1118, 1339

Byssal threads, 335, 468, 1071, 1099, 1158

C

Cadmium, 175, 214, 227, 385, 409, 603, 650, 735, 746-748, 760-763, 894, 903, 905, 1000, 1056

Cage(s), 440, 469, 608, 642, 757-758, 811, 907, 917, 921-924, 926, 928, 941, 959, 961, 999, 1054, 1061-1062, 1116, 1118, 1139, 1158-1159, 1185, 1190, 1198-1201, 1203-1205, 1208, 1241, 1267, 1323-1324, 1326, 1358, 1369-1370, 1373, 1376, 1379

Calcium, 246, 271-276, 282-284, 290-293, 295-296, 298, 312, 315

Calico scallops, 105, 107, 215, 406, 412-413, 565-566, 583, 588, 620, 626, 635, 639, 644, 646, 648, 652, 659, 667, 670, 678, 713, 716, 720, 727, 732, 737, 780, 796, 800, 823, 829, 841, 846, 855, 858, 862, 869-870, 945-947, 952-957, 961-965, 983, 1337-1338

Capture fisheries, 851-852, 869, 1031-1033

Carotenoids, 529

Cenozoic Era, 1, 3

Central nervous system, 193, 204, 214, 221, 328, 343, 348, 356, 381, 412

Chemical cues, 94, 110, 427

Chemoreception, 201, 335, 491, 542

Chemosensory structures, 86

Chromosome number, 545, 547, 568, 589, 592, 594, 1313

Chromosome preparation methods, 547

Chromosomes, 101, 181, 190, 543-548, 567-568, 579-580, 582, 585, 587, 589, 592-594, 1232, 1295, 1313, 1319-1320

Cilia, 56, 59-60, 63-64, 68-78, 80-82, 84-86, 91, 103, 105, 113, 118, 126-128, 131-132, 135, 137, 139-140, 144-145, 149-151, 154, 157-158, 178, 197, 199-201, 203-205, 212-213, 216, 225, 319, 355, 420, 422-424, 478, 614, 621-622, 624, 911

Ciliary activity, 84-86, 91, 106, 112, 210, 444, 448, 680-681

Ciliary transport, 79, 117

Clearance rate, 424-432, 434-435, 440-441, 450, 453, 481, 498, 749-751, 753, 761, 935, 1359, 1376

Cleavage, 51, 55, 61, 89, 99, 252, 275, 286, 288-289, 315, 545, 548-549, 591, 1099

Cold shock, 101, 457

Compensation index, 433, 441

Condition index, 470, 751, 759, 1257, 1273, 1373

 Culture systems, 1133, 1302, 1305, 1363
 Culture tanks, 532, 1361

D

D-larvae, 531, 578, 910, 1134-1135, 1234-1236, 1305, 1360-1361, 1363-1364
 D-veligers, 57, 92, 96-97, 99, 1268
 Daily growth lines, 111, 899
 Depuration, 748
 Detoxication of metals, 215
 Detritus, 417-418, 436, 477, 488, 521, 537, 605, 680, 695, 933, 994, 1104
 Development, 6-7, 27, 35, 45-46, 50-52, 54, 56, 58-59, 64, 68, 77, 80-81, 87-91, 94, 97-100, 103, 105, 108-115, 117-122, 139, 150, 170, 182, 188, 207-208, 215, 219, 223-224, 271, 273, 285, 309, 312, 318, 337, 359-360, 368, 371, 377-378, 383, 387-388, 408-410, 413, 422-424, 464, 521, 523, 526, 531-532, 540, 545, 550, 556, 562, 567, 581-582, 585, 592, 594-595, 604-605, 607, 611-612, 616, 618-619, 624, 630, 632, 637, 641-642, 649, 661, 666, 683, 712, 722-725, 727-728, 738, 750, 754, 759, 763, 772-773, 775, 783, 785, 797, 814, 827, 839, 848, 851-852, 855, 860, 863, 873, 876, 892, 901, 909, 911, 914, 928, 930, 932-933, 937, 940-941, 958, 961-962, 971, 973, 977, 979-980, 982, 984-988, 1000, 1005, 1015-1016, 1027, 1042, 1044, 1052, 1056, 1059,

- 1061, 1063, 1067, 1077, 1079-1080, 1083-1084, 1086-1087, 1099, 1104-1105, 1120, 1123, 1134, 1136, 1138-1139, 1141, 1150, 1152, 1154, 1177, 1181-1182, 1184, 1189, 1196-1197, 1201, 1205, 1207-1208, 1210-1211, 1215, 1219-1220, 1224-1225, 1233-1234, 1239-1240, 1243-1244, 1251, 1262-1263, 1269, 1275, 1277, 1287, 1289, 1293, 1295, 1300, 1307-1309, 1312, 1330, 1332, 1334, 1342-1343, 1348, 1350, 1356, 1379, 1392, 1404-1408, 1410-1411, 1418, 1421
- Development of the gill, 106, 212, 475
- Development of the gonad, 177, 1002
- Diatoms, 102, 143, 155, 212, 221, 417-418, 427, 435-436, 450, 452-453, 483, 486, 522, 528, 695, 927, 940, 943, 994, 1061, 1080, 1208, 1234, 1273, 1304, 1343
- Digestion, 85, 113, 150, 152-154, 159, 169, 219-223, 288, 313, 399, 401-402, 435, 438, 455, 475, 483-485, 491, 525, 539, 628, 635, 696, 731, 753, 757, 994, 1050, 1363, 1384
- Digestive diverticula, 221-222, 452, 525, 607, 617, 619, 621, 626-627, 646
- Digestive enzymes, 152, 154, 418, 525, 648
- Digestive gland, 66, 126-127, 130, 150-152, 154-157, 159-160, 162, 165, 169, 181, 191, 206, 209, 218-219, 226, 377, 380, 382, 391-393, 397-400, 402, 404-406, 435, 448, 450-451, 492, 525, 537, 542, 597, 600, 602, 604, 619-620, 624-626, 643, 746-747, 749, 763, 1000, 1002-1003, 1130, 1327-1328, 1416, 1425
- Digestive system, 150, 159, 212, 430, 536, 1188, 1368
- Dinoflagellates, 448, 453, 479, 483, 528, 636, 927, 934-935, 939, 1220, 1273, 1352
- Disease, 45, 103, 211, 407, 579, 596, 602, 605-612, 616-617, 620, 625, 627-628, 632, 635, 638-640, 642, 644-649, 748, 811, 830, 927, 963, 983, 999, 1047, 1084, 1350, 1353, 1379, 1416, 1424
- DNA, 4, 255, 543, 551-555, 562, 568, 580, 583-588, 590-594, 604, 616, 643, 671-672, 713, 716, 725, 742, 781, 846, 853, 981, 992, 1004-1005, 1010, 1045, 1058, 1324, 1333
- DNA markers, 560, 580, 590, 1005
- DNA polymerase, 552, 593, 742, 866
- Domoic acid, 893, 927, 931, 936-937, 939, 943
- Dredge fishery, 726, 834, 854, 1025, 1063, 1258, 1260, 1287, 1391, 1407, 1418, 1425
- Dredging, 440, 666, 694, 705, 712-713, 716, 718, 724, 730, 796-797, 805, 808, 810-811, 823, 832-835, 842, 846-847, 849-851, 854, 859, 898, 985, 995, 1018, 1020-1021, 1023-1025, 1027, 1029, 1033-1034, 1038, 1043, 1045-1046, 1048, 1061, 1078, 1085, 1192, 1251, 1261-1262, 1402, 1407, 1409, 1416-1418, 1421-1424, 1426
- ## E
- Egg development, 116
- Egg quality, 102, 541, 1061
- Egg size, 47-50, 54, 89, 112, 370, 911, 933, 1002
- El Nino Southern Oscillation (ENSO), 773, 775, 1399
- Electrophoresis, 4, 7, 543, 548, 551-553, 559, 571, 573, 593, 742, 866, 992, 1004, 1010
- Embryogenesis, 55, 87, 98, 114, 121, 986
- Embryonic shell formation, 107, 113
- Embryonic stages of bivalves, 100
- Embryonic survival, 577

Embryo(s), 51, 60, 84, 99-101, 105, 109, 111-112, 120-122, 391, 528, 545, 548-549, 592, 601, 635, 638, 739, 865, 958, 964, 1268
 Endoscopy, 104, 115, 132, 147, 213, 226, 423, 475, 491
 Energy acquisition, 417, 468, 476, 537, 1002, 1245
 Energy budget, 372, 384, 409, 461, 468, 479, 490, 493, 514, 518, 520, 741, 866, 1012, 1090, 1136
 Energy reserves, 87, 98, 121, 157, 380, 390-391, 406, 413, 479, 494, 542, 623, 706, 727, 943, 1003, 1367
 Enzymes, 100, 132, 152, 154, 157, 185, 214, 220, 398, 400-401, 535-537, 551, 553, 562, 573, 575, 588, 626
 Eocene, 11-12, 15-16, 18, 20-24, 28, 30-31, 34, 36, 38-39, 41-44
 Epifluorescence microscopy, 85, 113, 474
 Eurythermal, 30-31
 Excretion, 114, 162-163, 169, 175, 220, 223, 390, 395, 453, 467-468, 483, 494, 504, 517, 528, 746, 753, 943, 1000
 Eye-spots, 68, 72-73, 80, 1134
 Eyed larva, 983, 1304-1305
 Eyed veligers, 88

F

Fecundity, 107, 218, 361, 370-372, 376, 378, 380, 384-385, 393, 404, 407-408, 410, 458, 493, 502, 509-511, 513, 515-516, 518, 528-529, 536, 584, 715, 720, 766, 770, 794, 828, 849, 855, 882, 900, 907, 931, 1030, 1041, 1104, 1252, 1341-1342, 1414
 Feeding behavior, 427-428, 430, 437, 475, 526, 734
 Feeding inhibition, 445, 489, 491, 679, 742
 Feeding mechanisms, 119, 216, 1008
 Feeding physiology, 443, 475-476, 480-482
 Feeding rates, 89, 424-425, 427, 430-431, 445, 926
 Feeding response, 428, 452, 752, 1008
 Fertilization, 105, 108-109, 116, 121, 215, 219, 412, 584, 589, 593, 856, 861, 1245, 1332
 Fisheries management, 493, 714, 733-734, 759, 823, 830, 833, 835, 849-850, 852, 859, 861, 876, 888, 897, 988, 1018, 1033, 1036, 1042, 1051, 1385, 1392, 1397, 1401-1402, 1404, 1408, 1410, 1412, 1425
 Fishing intensity, 767, 797, 848
 Fishing mortalities, 819, 825
 Flame scallop, 317
 Food acquisition, 225, 490, 760
 Food availability, 384, 404, 411, 430, 432, 458, 462, 468, 475, 483-485, 497, 506-512, 518-520, 538, 669, 672, 677-678, 729, 880, 882, 900, 937-938, 1005, 1012, 1230-1231, 1246, 1248, 1253, 1257, 1318-1319, 1324, 1327, 1333, 1359
 Food dilution, 440-441, 443
 Food limitations, 443, 469, 471
 Food quality, 425, 437, 449, 451, 469, 484, 504, 648, 938
 Foot, 45, 61, 64, 68, 73, 75, 77-78, 80-81, 84, 91, 110, 124-126, 160-161, 167, 191, 200, 206-210, 253, 298, 335, 343, 461, 606, 624, 629, 784, 1009, 1071, 1085, 1276, 1304, 1361
 Foraminifers, 1209, 1273
 Fouling, 336, 470, 474, 596, 599, 601-603, 631-632, 637, 641, 643, 703, 748, 762, 914, 919, 921, 926, 932, 934, 959, 961, 1000, 1042, 1052, 1062, 1115, 1118, 1139, 1148, 1151, 1158-1159, 1189, 1201, 1203-1205, 1207, 1209-1211, 1217-1219, 1223, 1237-1238, 1267, 1305, 1318, 1323-1324, 1326-1327, 1329-1331, 1333, 1353, 1406, 1422
 Fouling organisms, 643, 914, 926, 1115, 1139, 1148, 1151, 1158-1159,

1204-1205, 1209-1211, 1318, 1324,
1327, 1329-1331
French scallop, 860, 1029-1030, 1065
Frontal cilia, 80, 131, 137, 141, 420,
423

- Gonad development, 177, 222, 224, 360, 374, 376, 378, 380-381, 388, 393, 397, 404, 408, 410, 413-414, 514, 538, 549, 752, 964, 1002, 1137, 1139, 1149
- Gonad epithelium, 402
- Gonad growth, 374, 376-377, 380, 391, 393, 404, 409, 417, 480, 550, 753, 1004, 1055, 1241
- Gonad index, 362, 367, 371-372, 374, 376, 378, 380, 384, 388, 391-393, 403, 461, 550, 579, 1001, 1012-1013, 1111-1112, 1149, 1151, 1303, 1368
- Gonad intestinal loop, 159, 183, 212, 402
- Gonad lipid accumulation, 400
- Gonad maturation, 357, 381, 391, 1006, 1322, 1326
- Gonad production, 497, 549, 572, 909
- Gonad recovery, 1078
- Gonad size, 359-360
- Gonad structure, 177, 1000
- Gonad weight, 360, 362, 365-367, 370-371, 373, 391, 393, 405, 794, 915, 1001, 1070, 1149
- Gonadosomatic index, 510, 1078, 1343
- Great scallop, 105, 115-116, 118-119, 584, 587, 617, 631, 644, 646, 652-653, 716, 719, 725-726, 730, 853, 991, 993, 1041, 1045-1046, 1053, 1056, 1060, 1062, 1064, 1067, 1078, 1086-1089, 1143, 1153
- Growout, 941, 981-983, 1233, 1236-1237, 1239, 1243, 1327, 1357-1358, 1366-1367, 1372-1375, 1379, 1385
- Growth curve, 472, 495-496, 1253, 1323, 1345-1346, 1373

Growth efficiencies, 88, 490, 494-495, 498, 500, 504, 506, 520, 912, 937, 1070-1071, 1090, 1104
 Growth inhibition, 447, 451, 750, 754-755, 1200
 Growth models, 471, 996, 1012, 1035, 1055
 Growth rings, 58, 472, 501, 869, 871, 904, 993, 996, 1007, 1230, 1251-1252, 1398, 1410
 Gut contents, 418, 420, 424, 694-695, 926, 994, 1273

H

- Hanging culture, 490, 741, 917, 1055, 1059, 1063, 1065, 1080, 1088, 1091, 1093-1094, 1105, 1111-1112, 1116, 1119-1120, 1125, 1127, 1129, 1133, 1135-1136, 1138, 1140, 1197-1199, 1201-1203, 1332, 1373, 1422-1423
 Hardy-Weinberg, 555-556, 563-564, 568-570, 588
 Harmful algal blooms, 417, 451, 475, 482, 752, 961, 1027, 1237, 1417
 Harvesting, 357, 457, 665, 770, 785, 789, 791, 796, 822, 824-825, 828-829, 832, 834, 839, 844, 851, 858, 876, 883, 889-890, 892-893, 896, 901, 907, 960, 971-972, 1075, 1078-1079, 1091, 1121, 1201, 1258, 1290, 1332, 1350, 1354, 1402, 1424
 Hatcheries, 83, 103-105, 108, 117-118, 357, 401, 403, 448, 452, 521-522, 528, 534-535, 537, 539, 541, 567, 569, 572, 577-579, 581-582, 595, 597-598, 605-607, 609, 611-612, 636, 638, 640, 642-643, 648, 683, 712-713, 742, 907-909, 911-912, 916, 918, 930, 933, 935-938, 940, 942-943, 958-961, 963, 974-975, 980-984, 997, 1000, 1003-1005, 1010, 1013-1014, 1033, 1047, 1060-1061, 1063, 1065, 1077-1082, 1087, 1135, 1151-1152, 1154-1155, 1157-1159, 1161, 1233-1235, 1239-1240, 1242-1243, 1248-1249, 1269, 1283, 1300-1301, 1303-1305, 1307, 1309, 1311, 1313, 1322, 1326, 1329-1330, 1333-1334, 1357-1360, 1363, 1365, 1367-1368, 1374, 1379, 1385, 1387-1388, 1396, 1398, 1405-1408, 1410
 Hatchery culture, 103, 582, 712, 937, 982, 1033, 1301, 1313
 Heart scallops, 162
 Heat shock, 101, 549, 592
 Heavy metals, 100, 762-763, 883, 894, 898, 925, 1009, 1046, 1057, 1208, 1273
 Hemocytes (haemocytes), 113, 132, 137, 144, 147, 149, 165, 168-170, 172, 178-179, 181, 183, 185, 188, 214, 224, 399, 401-402, 450, 597, 605, 607, 609-611, 614, 617, 625-626, 635, 644, 1235, 1246
 Hemolymph (haemolymph), 141, 144, 147, 159, 163, 167-168, 170-172, 178-179, 188, 199, 208, 214, 221, 224, 381, 400, 402, 406, 466, 533, 595, 604, 633, 635, 757, 762, 1377
 Hepatic artery, 161
 Hermaphrodites, 176-177, 415, 544, 550, 569, 578, 948, 953, 974, 1000, 1010, 1012, 1172, 1178, 1231, 1241, 1252, 1272, 1295, 1317, 1319-1320, 1340, 1368, 1396, 1413
 Hermaphroditic species, 176, 557
 Hinge, 7, 11-13, 17-18, 23-26, 28, 31, 49, 57-59, 61, 64, 66, 68, 82-83, 94, 107, 113-114, 116-117, 124, 126-127, 130, 198, 220, 230, 254, 330, 335, 337, 339-340, 348, 350, 409-410, 472, 484-485, 495, 630, 637, 687, 696, 698-700, 716, 728, 811, 869, 974, 985-988, 993, 1099, 1182
 Histology, 109, 122, 155, 157-158, 177, 195-197, 199, 208, 212, 216, 362, 365-368, 370, 381, 404, 1000
 Histology of larvae, 106

Horse mussels, 1034
 Hydrothermal vent species, 46, 50

I

Iceland scallop, 105, 110, 120, 225, 409,

- Larval dispersal, 51, 670, 676, 683, 720, 778, 782, 785, 789, 849, 867, 1042, 1257
- Larval distribution, 45, 90, 98, 880, 949, 1137
- Larval eyes, 78
- Larval feeding, 911
- Larval growth, 89, 101, 105, 108, 111, 401, 403, 405, 531, 536, 549, 576-578, 581-582, 584, 937, 939, 942, 1036-1037, 1182, 1234, 1268, 1323, 1363-1365, 1367, 1381, 1384
- Larval heart, 79
- Larval hinge, 58-59, 113, 728
- Larval mortalities, 118, 452, 483, 600-601, 609, 648, 939, 1234-1235
- Larval movements, 94
- Larval muscles, 81
- Larval nervous system, 45
- Larval origin, 120, 865

Larval period, 98, 531, 1234, 1242, 1304
 Larval phase, 99, 529, 536, 670, 878, 1353, 1396, 1398
 Larval production, 113, 410, 932-933, 958, 1234
 Larval retention, 670, 672, 765, 778, 782, 784-785, 833, 865, 879, 1011, 1257
 Larval settlement, 104, 117, 369, 666, 677, 679, 681, 689, 691, 718, 771, 789, 791, 863, 911, 940, 976, 1013, 1157, 1263, 1304, 1361, 1363-1364, 1383, 1396, 1411
 Larval shell, 46, 50, 56, 58-59, 66, 89, 91, 106, 111, 113, 450, 1172, 1182, 1234
 Larval size, 87, 578, 1268, 1361
 Larval stages, 69, 95, 428, 577, 683, 772, 958, 1155, 1299, 1366
 Larval survival, 88, 102, 107, 112, 385, 408, 448-449, 529, 579, 588, 645, 720, 771, 773-774, 849, 910-911, 958, 1013, 1041, 1073, 1245, 1300, 1364, 1368
 Larval tissues, 90, 103, 606
 Larval transport, 670, 774, 879, 900, 1006
 Larval viability, 529, 541, 579, 933
 Larval vigour, 909
 Lateral cilia, 137, 423, 447, 480
 Latero-frontal cilia, 137, 143, 211, 423
 Licenses, 837-838, 841, 855, 894, 960, 1025, 1079, 1354, 1356, 1402, 1420
 Ligament, 58-59, 82, 126, 130, 220, 222, 225, 335, 337, 339-340, 501, 589, 901, 1072, 1099, 1252, 1273, 1324
 Lipid, 45, 69, 84, 87, 91, 102-103, 107-108, 119, 132, 156-157, 168, 183, 269, 390, 392-393, 395-398, 400-401, 403, 405, 413, 415, 427, 437, 470, 486, 522, 526, 528-531, 533-542, 577, 909-912, 932, 939-940, 942, 1002-1003, 1037, 1053, 1130, 1255, 1290, 1320, 1327, 1364, 1368

Lobsters, 630, 685, 893, 899, 903, 926, 937, 1404, 1410

M

Magnesium, 173, 236, 239, 283, 312, 343, 747
 Manganese, 214, 747
 Mantle, 56, 58, 60, 64-65, 68, 72, 74-82, 85-86, 99, 108, 124-132, 139, 142-143, 160-162, 167, 191-192, 196-200, 213, 222-223, 253, 255, 317-318, 328-330, 332-337, 340-345, 348-351, 402, 452, 457, 595-598, 600, 603, 607, 614, 618, 621, 624, 627, 630, 632-633, 635-636, 638, 699, 707, 811, 1187-1188, 1273, 1353
 Mantle cavity, 73, 78, 86, 222, 229, 335-339, 345, 420, 464, 596, 618, 621-623, 630, 632, 651, 689, 692, 695-696, 699-700, 745, 993-994, 1417
 Mantle curtain, 124, 127, 351
 Mantle eyes, 191, 224, 355, 635
 Mantle structure, 81
 Mantle tentacles, 82, 341
 Mantle tissue, 76, 635
 Mariculture, 484, 506, 537, 940, 963-964, 1093-1094, 1098-1100, 1111, 1133, 1141, 1143, 1154, 1170, 1196-1197, 1201-1202, 1204-1205, 1207-1211, 1213-1224, 1232-1233, 1244, 1382,
 Mesh size, 471, 805, 808, 839, 885, 920, 922, 942, 964, 1020, 1024, 1113, 1115-1116, 1266, 1276

 Molecular evolution, 34, 36-37, 41, 584, 587, 1040
 Molecular phylogenies, 7, 35, 41, 585
 Mortality, 99, 110, 118, 135, 340, 353, 386, 412, 449-453, 476, 483-484, 489, 495, 504, 511, 514-517, 534, 569, 579, 584, 586, 605-606, 608, 619, 630, 635-636, 640-642, 644, 646, 648, 666, 677, 681-684, 687-688, 717, 719-721, 724-726, 728, 730-733, 735-737, 739, 748-749, 752, 759, 765, 767, 770-771, 776, 778, 786, 789, 794-795, 797-799, 804, 808, 810-811, 814, 818, 824, 831, 839, 841-844, 847, 849-850, 853, 858-859, 887, 889, 894, 896, 898, 911, 920-921, 929, 932, 937, 939, 943, 950, 954, 958-961, 963, 970, 977, 979, 983, 998-999, 1008-1009, 1013, 1022, 1035, 1038, 1044-1047, 1050-1051, 1062, 1064, 1073, 1081-1083, 1088, 1105, 1116, 1118, 1125, 1127, 1129, 1138-1139, 1151, 1153-1154, 1158-1161, 1170, 1184, 1199, 1201-1202, 1222, 1228, 1234-1235, 1237, 1254, 1257, 1269, 1274, 1285, 1305, 1319, 1323-1324, 1327, 1330-1331, 1350, 1353, 1365, 1373, 1377-1379, 1382,

1396-1398, 1406, 1409, 1414-1417, 1422, 1425
 Mucocyte(s), 128, 130-132, 139-140, 145-148, 212-213, 216
 Mucus, 78, 84, 133, 135, 137, 139, 141-142, 145-147, 150-152, 159, 168, 204, 206, 212-213, 219, 420-421, 432, 448-451, 482, 635, 640, 666, 753
 Muscle cells, 163-164, 179, 229, 231, 234, 240, 265, 301, 305
 Muscle contraction, 229, 272, 279, 299, 301-304, 311, 314, 346, 390
 Muscle fibres, 64, 137, 147, 158, 162-163, 165, 178, 201, 203, 208, 210, 232, 244, 280, 283, 290, 297, 312, 318, 347, 611, 634, 1343
 Muscle myosins, 253, 261, 263, 265-267, 270, 277-278, 282, 284-285, 287, 295, 298, 300-302, 304-305, 308-310, 312-316
 Muscle physiology, 289, 302
 Mussel farm, 1214, 1217, 1221
 Mussel mariculture, 1224

N

National Marine Fisheries Service (NMFS), 713, 737, 816, 829, 867, 877, 900, 937, 950, 952-953, 956, 961-963, 986, 988, 1087-1088, 1090
 Natural mortality, 630, 687-688, 719, 721, 724, 730, 732, 808, 811, 818, 824, 841, 850, 853, 950, 970, 979, 998, 1008-1009, 1045, 1170, 1257, 1285, 1353, 1377-1378, 1396, 1398, 1406, 1409, 1415, 1417
 Necrosis, 103, 113, 185, 448, 450-452, 595, 601, 605-606, 610-612, 638, 645-646, 649, 1051, 1084, 1088, 1333
 Nerves, 74, 78-79, 129-130, 167, 191-196, 198-199, 204, 208, 218, 290, 322, 328, 330-332, 343-346, 348-352

Nervous system, 45, 78-79, 81, 86, 90, 126, 191, 193, 204-206, 214-215, 221, 317, 328, 335, 343, 346, 348, 353, 356, 381, 390, 412
 Net efficiencies, 506
 Net growth efficiency, 490, 494, 500, 520, 1070, 1090, 1104
 Net production efficiency, 516
 Net somatic growth efficiency, 495
 Nitrogen, 173, 265, 395, 417-418, 437, 440, 444, 467, 478, 480, 494, 522, 525, 530, 535, 936, 1220, 1257
 Nitrogen excretion, 467, 517
 Nursery culture, 944, 1235, 1239
 Nutritional requirements, 417, 521, 526, 528-529, 533, 536, 1005, 1210
 Nutritive stress, 467, 479

O

Oöcyte(s), 159, 169, 178, 181-186, 190, 212, 361, 544, 1002, 1234-1236, 1295
 Oöcyte degeneration, 408
 Oöcyte development, 368, 377, 388
 Oöcyte growth, 377, 379, 382, 393, 398, 414
 Oöcyte maturation, 378, 401
 Oöcyte size, 372, 383, 388
 Oögenesis, 377, 382, 398, 400, 407-408, 410, 458
 Oral groove, 133, 141, 144, 146-148, 150
 Ordinary filament, 133, 137, 139, 141, 143
 Organic pollution, 1205
 Organogenesis, 59, 115, 176
 Oxyconformers, 455
 Oxygen, 86, 88, 265, 385, 387, 395-396, 405, 455, 457, 464, 466-467, 481, 484, 605, 681, 740, 743, 783, 794, 810, 869, 904, 996, 1005, 1042, 1164, 1167-1168, 1205, 1208, 1210, 1303-1304
 Oxygen concentration, 477, 677

Oxygen consumption, 88, 111, 114, 390, 395, 432, 453-454, 459, 461-464, 474-476, 483-485, 487-490, 517, 640, 667, 717, 731, 935, 943, 1008, 1012, 1050, 1090, 1104, 1138, 1377
 Oxygen levels, 88, 444, 457
 Oxygen tension, 444, 453, 455-457, 465, 475, 680
 Oxygen uptake, 167, 213, 431, 456, 458-462, 489, 492, 499, 504, 1057, 1377
 Oxyregulation, 455, 457

P

Paralytic shellfish poison (PSP), 103, 418, 476, 893, 927, 931-932, 937, 942-943, 977, 1024, 1130, 1273, 1352
 Parasites, 385, 453, 595-596, 607, 609-610, 617, 619-620, 626, 632, 638, 640-643, 645, 649, 748, 805, 927, 930, 939, 999, 1009, 1084, 1187-1188, 1218-1219, 1396, 1398, 1416
 Parasitic castration, 385, 413
 Particle processing, 132-133, 135, 141, 144, 212-213
 Particle retention, 132, 143, 221, 223, 420-424, 427, 478, 481, 485, 487, 489, 1057, 1090
 Particle selection, 141, 143-144, 212, 218, 432-435, 441, 481-482, 488, 491, 695, 943, 994
 Particle sorting, 226, 434, 491
 PCBs, 748, 750, 1088
 PCR, 4, 252, 255, 552-553, 555, 561-563, 568, 593, 742, 1004-1005, 1058, 1078
 Pearl nets, 446, 469-471, 481, 907, 916-920, 924, 928, 932, 934, 959, 1085, 1301-1302, 1305, 1309, 1323-1324, 1326, 1329, 1331
 Pearl oysters, 208, 452, 484, 646, 1330
 Pediveliger(s), 45, 58-59, 64, 68, 73-76, 78-82, 84-86, 89, 91-93, 95, 97, 108, 531, 795, 910, 914, 959, 1099,

- 1134-1135, 1234-1236, 1304, 1361, 1363

- Shell gland, 56, 58-59, 68
- Shell growth, 46, 58, 89, 119, 432, 439, 445-446, 450, 470-472, 487, 493, 495-496, 506-507, 519, 895, 923, 997, 1054, 1061, 1083, 1086, 1147, 1164, 1166, 1180, 1230
- Shell height, 29, 360, 367, 371, 384, 390, 424, 428-429, 431, 444-445, 451, 453, 457-458, 468-472, 474, 495, 550, 573, 611, 616, 668, 679, 682, 685, 690-692, 700-701, 704, 725, 869, 888, 893, 903, 905, 916-917, 921-923, 954, 958, 967, 969-970, 973-974, 976-977, 979-983, 999, 1006, 1008, 1011-1012, 1021, 1061-1062, 1071, 1083, 1120, 1146-1150, 1152, 1154, 1165-1167, 1169-1173, 1177-1178, 1180-1181, 1185, 1188, 1194, 1196, 1200-1201, 1225, 1231, 1234, 1237, 1241, 1252, 1266, 1272-1274, 1295-1296, 1298, 1303, 1306, 1315, 1319-1320, 1325, 1327-1328, 1341-1342, 1345-1346, 1353-1354, 1361-1362, 1365-1366, 1369, 1372-1376, 1378, 1398, 1417
- Shell height-meat weight allometry, 903
- Shell height standards, 893

- Shell length, 50, 89, 495, 571-572, 579, 587, 681, 685, 689, 693, 703, 708, 793, 993, 995-996, 998, 1005, 1020, 1024-1025, 1061-1062, 1102, 1116, 1121, 1136, 1152, 1226, 1234, 1318-1319, 1323-1324, 1327, 1329, 1331, 1366, 1373, 1376, 1396, 1415
 Shell margin, 124, 126, 130, 332, 336, 350, 466, 697
 Shell matrix, 497, 637
 Shell microstructure, 7, 11, 16, 131, 600
 Shell morphology, 6, 89, 109, 111, 115, 336, 593, 662, 742, 1039, 1099, 1146, 1227
 Shell production, 494, 501-503, 1086, 1094
 Shell rings, 1011, 1230
 Shell secretion, 56, 58-59, 80, 85, 118
 Shell size, 11, 89, 444, 495, 566, 572-574, 690, 869, 885, 894, 929, 1074, 1105, 1112, 1182, 1231
 Shell structure, 225, 1172, 1182
 Shell valves, 56, 58, 60, 64, 69, 91, 127, 335, 439, 687, 689, 869, 1099, 1188
 Shell width, 49, 550, 579, 1366-1367, 1384
 Shelled veliger stages, 1005
 Shucking, 835, 874, 972-973, 1024, 1074, 1355, 1404, 1420
 Silt, 94, 444, 475, 679-681, 691, 743, 763, 783, 810, 864, 1005, 1200, 1207, 1416-1417, 1425
 Size composition, 729, 883, 1222, 1272, 1318, 1344
 Size limit, 143, 424, 825, 876, 888-889, 973, 1076, 1154, 1262, 1346, 1354, 1403-1404, 1421
 Smooth adductor muscle, 125, 243-246, 248, 255, 271, 282, 293-294, 309, 332-333, 335, 348-351
 Spat, 29, 54, 59, 80-81, 83, 85, 88, 93-94, 97, 104-106, 110-111, 115, 117, 120, 357, 362, 365-366, 369, 386, 404, 406, 450, 457, 469-471, 478, 480, 482, 489, 536-538, 541, 563, 572-573, 582, 589, 601, 631, 641, 646, 670-672, 675, 677, 679-681, 684-685, 691, 693-694, 702, 713-714, 717, 719-721, 725, 731, 735, 741-742, 744, 770, 774-776, 778, 783, 794, 810, 835, 843, 846, 879-880, 901, 907-920, 924-925, 928-931, 933-943, 961, 975, 988, 996-1000, 1003, 1005-1011, 1013-1014, 1029, 1032-1033, 1036-1039, 1042-1044, 1046-1047, 1049, 1051-1053, 1056-1062, 1064-1065, 1070, 1076-1077, 1079-1083, 1085, 1087-1088, 1090-1091, 1099, 1102, 1104, 1111-1116, 1120-1121, 1124, 1130, 1134-1138, 1155, 1157-1158, 1172, 1176, 1182-1183, 1185, 1187, 1197-1199, 1202-1203, 1205, 1208, 1211, 1213, 1215, 1233-1237, 1242, 1247-1248, 1263-1266, 1268, 1286, 1288, 1290, 1301, 1322-1323, 1326, 1329-1330, 1353, 1357-1359, 1365-1372, 1374, 1376, 1378-1379, 1383, 1387-1389, 1396, 1398, 1401, 1405-1408, 1411, 1415, 1417, 1420, 1422-1424
 Spat bags, 914, 916, 1155
 Spat collection, 120, 641, 741-742, 846, 908-909, 912-914, 916, 925, 928, 931, 936-937, 1006, 1038, 1056-1057, 1059-1062, 1077, 1090-1091, 1111-1113, 1115-1116, 1121, 1124, 1130, 1135, 1137-1138, 1172, 1182-1183, 1197-1198, 1233, 1242, 1247, 1263-1265, 1268, 1288, 1322, 1369-1372, 1387, 1398, 1405-1407, 1423
 Spatfall, 738, 863, 867, 914, 975, 1199, 1370, 1406, 1411-1412
 Spawning, 51, 83, 89, 95, 98-99, 101-102, 104-107, 116, 121, 177, 179-180, 185, 198, 206, 212-213, 217, 221, 223-224, 357-358, 360, 362, 365-366, 368-373, 375-376, 378-391, 397-398, 400-401, 403-416, 418, 447, 471, 476, 493, 496, 507,

- 514, 521, 529, 549, 584, 591, 597, 615, 620, 636, 666, 683, 706, 711-712, 717, 720, 732, 737, 743, 769-777, 780, 782, 788, 791-792, 825-829, 832-833, 836, 839, 841-842, 844-846, 849, 856, 861, 879-880, 882, 889, 909-910, 914-915, 919, 924, 936, 939, 942, 948-949, 953-954, 958, 960-961, 963, 969, 974, 976, 988, 997, 1001-1004, 1006, 1010, 1012-1013, 1029-1030, 1039, 1041, 1050, 1054, 1058, 1060, 1066, 1070, 1076, 1078-1079, 1085-1086, 1089-1090, 1099, 1104, 1111, 1134-1135, 1138, 1149-1152, 1155, 1157, 1166, 1170, 1181, 1198-1199, 1206, 1234-1235, 1237, 1241-1242, 1249, 1251-1252, 1255, 1257, 1260-1262, 1266, 1268, 1272-1273, 1295, 1301, 1303, 1305, 1307, 1317-1320, 1322-1323, 1326, 1334, 1340-1344, 1353, 1358-1362, 1367-1369, 1371, 1378-1379, 1384, 1386, 1389, 1403, 1411, 1414-1415, 1421
- Spawning period, 89, 101, 372, 375, 379, 388, 408, 447, 636, 909, 914, 974, 1001, 1004, 1085, 1343, 1378
- Spawning season, 381, 418, 772-773, 879, 909, 1002-1003, 1104, 1134-1135, 1155, 1260-1261, 1342, 1353, 1369, 1378
- Spawning stage, 915, 1149, 1343
- Spawning stimulus, 101, 387-390, 405
- Specific growth rates, 904, 1071
- Spermatozoa, 101, 110, 184, 188-190, 361, 387, 403, 544-545, 548, 586, 792, 936, 1104, 1295, 1303
- Spiny scallop, 111, 937, 945, 972, 975-980, 984, 986-987
- Sponges, 340, 353, 355, 608, 611, 636-637, 639, 641, 647, 649, 708, 718-719, 736, 969, 1009, 1011, 1151, 1164, 1188, 1273, 1283, 1348, 1422
- Starfish, 226, 317, 333-335, 340, 342-345, 348-351, 354, 356, 461-462, 465, 574, 637, 684-685, 687-688, 694, 707-708, 710, 717-718, 722, 727-728, 730, 742, 843-844, 914-916, 921, 923-924, 926, 993, 999, 1007, 1009, 1012, 1046, 1051, 1071, 1086, 1120, 1185, 1200, 1202-1203, 1208, 1257, 1396, 1405, 1416
- Stock abundance indices, 1073
- Stock biomass, 879, 887, 1030, 1074
- Stock rehabilitation, 876, 890
- Stock size, 771, 774, 777, 803, 816, 818, 824, 828, 830-831, 887, 995, 1029, 1276, 1399
- Striated adductor muscle, 125, 229, 231-234, 238, 241, 253, 255, 263, 265, 267, 271, 282, 294-295, 301, 305-306, 308-309, 311-312, 314, 734
- Suspension feeding, 80, 87, 119, 218, 221, 226, 417-418, 421, 424, 427, 435, 445, 447, 478, 480-483, 485, 488, 490-491, 749, 753, 761, 793-794, 844, 1037, 1426
- Swimming activity, 88, 448, 461, 464-465, 688, 704-706, 710, 882, 885, 994, 1368
- Swimming behaviour, 92, 99, 108, 350, 352, 478, 627, 689, 698, 705-706, 708, 715, 719, 721, 726, 730, 734, 1036, 1040
- Swimming frequency, 704, 727
- Swimming movements, 651, 673, 689, 700, 719, 994, 1255
- Swimming path, 84, 92
- Swimming speed, 691, 703, 719, 1040, 1071

T

- Tagging, 677, 709, 711, 717, 723, 733, 736, 994-996, 998, 1009, 1022, 1035, 1038, 1044, 1065, 1396, 1398, 1415-1417
- Teeth, 7, 18, 23-26, 28, 47, 49, 58-59, 82, 130, 796, 839, 1018-1020, 1030, 1182

Temperature effects, 224, 414-415, 542, 715, 931, 1389
 Temperature optima, 99
 Temperature requirements, 372
 Temperature tolerance, 99-100, 116, 121, 667-668, 682, 733, 735, 935, 1008, 1052
 Tentacles, 86, 110, 115, 121, 127, 130, 167, 191, 196, 198-199, 221, 318, 332-333, 335, 341-343, 345, 598, 635, 696, 707, 1315, 1317
 Tentacular ganglion, 121
 Testes, 389, 894
 Thermal shock, 99, 101, 666, 705, 1360-1361
 Thermal stimulation, 377, 381, 387, 403, 910, 1234, 1268, 1303
 Thermal tolerance, 121, 903
 Tidal rhythm of extracellular digestion, 219
 Tidal rhythm of feeding, 221
 Toxic algae, 101, 447-448, 927, 988, 1055
 Toxic algal blooms, 448, 484, 943, 997, 1005, 1417, 1424
 Toxic dinoflagellates, 479, 483, 927, 934-935, 939, 1352
 Toxic phytoplankton, 491, 929, 1140, 1383
 Toxicity, 105, 113, 116, 214, 221, 449, 451-452, 478, 485, 598, 601, 603, 636, 638, 735, 748-751, 753, 756, 760-762, 930, 934, 936, 1013, 1037, 1047
 Toxicity levels, 893
 Toxin(s), 103, 447-448, 450, 452, 474-476, 893, 926-927, 931-934, 936-937, 939, 944, 980, 984, 1024, 1027, 1043, 1130, 1140, 1352, 1417
 Trace minerals, 533
 Trawl fisheries, 799, 977-978, 1007, 1053, 1320-1321, 1391, 1395, 1403-1404, 1408, 1410
 Trawlable species, 1403
 Trawlers, 664, 711, 795, 797, 803, 823, 1024-1025, 1074-1075, 1242-1243,

Veliger locomotion, 112
Veliger shell, 100
Veliger stages, 68, 80, 85, 90-91, 95,
1005
Velum, 45, 57, 59-61, 63-66, 68-70, 78-
82, 84-87, 91, 108, 124-127, 130,
200, 332, 336-337, 342, 344-345,
606, 692, 704, 911, 1361, 1368
Ventral groove, 432
Ventral margins, 11, 15, 124, 126, 133,
146-147, 162, 337, 350, 421, 495,
637, 694, 967, 1200
Vibriosis, 118, 605-606, 612, 640, 1235,
1333, 1368, 1388
Virus(es), 103, 552, 595, 601-602, 604-
605, 639, 641-644, 646, 999, 1051,
1084, 1086, 1088, 1416, 1425
Viscera, 126, 193, 196, 626, 635, 1273,
1281, 1354-1355, 1420
Visceral arteries, 161
Visceral ganglia, 191, 381
Viscosity, 130-131, 133, 137, 141, 146-
147, 150-152, 316, 753, 1273
Vitamin deficiencies, 533
Vitamin requirements, 119, 533, 535
Vitellogenesis, 181-182, 184-185, 358,
380, 382, 393, 399, 404
Von Bertalanffy equation, 506-507,
1376

W

Weathervane scallops, 409, 411, 483,
518, 738, 797, 845, 967-973, 979,
981, 983-984, 986-988
Wet weight(s), 396, 421-422, 524, 527,
1000, 1213, 1231, 1303, 1376
Whelks, 1396

X

X-ray diffraction, 175, 235, 237, 240,
242, 245, 247, 299, 301, 307

Y

Yesso scallop, 614, 616, 1163, 1174-
1183, 1189-1194, 1196-1197, 1203-
1205, 1208, 1211, 1215, 1222
Yezo scallop, 225, 643, 652, 741

Z

Zhikong scallops, 1143, 1146-1151,
1153-1155, 1157-1159
Zinc, 112, 175, 200, 219, 601, 638, 643,
747, 763, 894, 903, 1273
Zoogeography, 722, 729, 741, 1087-
1088
Zooplankton, 477, 1211, 1369
Zoospores, 452, 612, 616
